Preface	xv
----------------	-----------

VOLUME 1

Chapter 1	Management of Carotid Stenosis: Carotid Revascularization in the Modern Era <i>Pratik Bhattacharya</i>	1
Chapter 2	Ischemic Stroke: From Acute Treatment to Long-Term Recovery <i>Fabrizio Sallustio, Silvia Di Legge and Giacomo Koch</i>	13
Chapter 3	Ischemic Stroke Prevention in Vietnam <i>Chung Thanh Nguyen, Dinh Van Tran and Andy H. Lee</i>	55
Chapter 4	Modulation of Protein Kinase C Isoforms: A Potential Therapeutic for Ischemic Stroke? <i>Ryan C. Turner, Brandon Lucke-Wold, Zhenjun Tan, Charles L. Rosen and Jason D. Huber</i>	63
Chapter 5	Role of Transcranial Doppler Ultrasonography in Cerebrovascular Disease <i>Aftab Ahmad and Vijay K. Sharma</i>	83
Chapter 6	Inflammation in Ischemic Stroke: Mechanisms, Diagnosis and Management <i>Anna Woodbury, Osama Mohamad, Shan Ping Yu and Ling Wei</i>	101
Chapter 7	Ischemic Stroke Susceptibility Gene Research: Lessons We Learned <i>Bela I. Meleggh, Anita Maasz, Peter Kisfali, Katalin Sumegi, Balazs Duga, Gyorgy Kosztolanyi, Samuel Komoly and Bela Meleggh</i>	129
Chapter 8	Perioperative Ischemic Stroke <i>Richard Shek-kwan Chang, Windsor Mak, Raymond Tak-fai Cheung and Shu-leong Ho</i>	157

Chapter 9	Traditional Medicine in the Treatment and Prevention of Ischemic Stroke <i>Amy C. Y. Lo and Di Yang</i>	175
Chapter 10	Ischemic Stroke in Children: Symptoms, Prevention and Recovery <i>Mubeen F. Rafay</i>	219

VOLUME 2

Chapter 11	The Immune System and Strokes <i>Manzoor A Mir, Raid S Al-Baradie and Malik D Alhussainawi</i>	253
Chapter 12	Pathophysiology of Strokes <i>Manzoor A. Mir, Raid S. Al-Baradie and Malik D. Alhussainawi</i>	277
Chapter 13	Inflammation and Anti-Inflammatory Agents in Strokes <i>Manzoor A. Mir, Raid S. Al-Baradie and Malik D. Alhussainawi</i>	333
Chapter 14	Major Advances in the Treatment of Strokes <i>Manzoor A. Mir, Raid S. Al-Baradie and Malik D. Alhussainawi</i>	363
Chapter 15	Stem Cells and Treatment of Strokes <i>Manzoor A. Mir, Raid S. Al-Baradie and Malik D. Alhussainawi</i>	429

VOLUME 3

Chapter 16	An Introduction to Cerebrovascular Diseases <i>Manzoor A Mir</i>	457
Chapter 17	Immunobiology of Stroke <i>Manzoor A. Mir</i>	493
Chapter 18	Natural Herbs, Human Brain and Neuroprotection <i>Manzoor A Mir</i>	563
Chapter 19	Natural Herbs in Stroke Prevention and Treatment <i>Manzoor A. Mir and Raid S. Al-Baradie</i>	625
Chapter 20	Polyphenols from Natural Herbs in Neuroprotection <i>Manzoor A Mir</i>	661

VOLUME 4

Chapter 21	Recession, Skills and National Development: The South African Case <i>Salim Akoojee</i>	695
Chapter 22	Foreword Advances and Challenges in Stroke: How Are Modern Techniques Changing Our Understanding of Stroke? <i>Michelangelo Mancuso</i>	711

Chapter 23	Monogenic Diseases Associated with Stroke <i>V. Montano, N. Giannini, M. Maccarrone, C. Simoncini, E. Ferrari, L. Ulivi, G. Siciliano, U. Bonuccelli and M. Mancuso</i>	713
Chapter 24	Fabry Disease: An Introduction for Neurologists <i>Atul B. Mehta</i>	731
Chapter 25	Pathogenesis of Hemorrhagic Stroke <i>A. Bersano</i>	747
Chapter 26	Animal Models of Stroke: Present and Future <i>B. Casolla, S. Candela, A. Ciacciarelli and F. Orzi</i>	771
Chapter 27	The Added Value of Neurosonology A Tax-Free Genius in the Probe <i>A. Chiti and M. Del Sette</i>	779
Chapter 28	Intravenous Thrombolysis: Present Evidences and Future Perspectives <i>Danilo Toni and Alessio Pieroni</i>	793
Chapter 29	Haemorrhage: Emerging Therapies <i>Valentina Arnao and Maurizio Paciaroni</i>	805
Chapter 30	Management of Intracranial Stenosis <i>Valentina Arnao and Maurizio Paciaroni</i>	817
Chapter 31	“Telestroke,” a Frontier in the Globalization Era <i>C. M. Klingner, O. W. Witte and A. Günther</i>	827
Chapter 32	Imaging in Acute Stroke <i>Mirco Cosottini and Graziella Donatelli</i>	851
Chapter 33	Stroke and Atrial Fibrillation <i>E. Soldati, F. Menichetti and M. G. Bongiorno</i>	873
Chapter 34	Subclinical Atrial Fibrillation (SCAF) and Embolic Stroke of Undetermined Source (ESUS) <i>Alberto Chiti</i>	889
Chapter 35	Direct Oral Anticoagulants in Patients with Atrial Fibrillation <i>Isabella Canavero and Giuseppe Micieli</i>	905
Chapter 36	Emerging Biochemical Risk Markers of Stroke <i>M. Franzini, M. Emdin and A. Paolicchi</i>	927
Chapter 37	Mitochondria, Mitochondrial DNA and Stroke <i>M. Maccarrone, E. Caldarazzo Ienco, N. Giannini, V. Montano, A. Lo Gerfo, D. Orsucci, U. Bonuccelli, M. Mancuso and G. Siciliano</i>	941
Chapter 38	Cervical Artery Dissection: What’s New in 2015 <i>Stéphanie Debette</i>	955

VOLUME 5

Chapter 39	New Insights in Ischemic Stroke: Role of Antioxidant Supplementation <i>Ramón Rodrigo, Andrés Miranda-Merchak, Rodrigo Gutiérrez and Rodrigo Fernández</i>	971
Chapter 40	Mechanisms Underlying Ischemic Stroke Prevention by Tea (<i>Camellia Sinensis</i>) <i>Yuri N. Clement</i>	1011
Chapter 41	Neonatal Asphyxia and Stroke: Morbidity, Models, Consequences, and Treatments <i>J. R. Rivers and J. C. Ashton</i>	1027
Chapter 42	Swallow Screening as an Essential Component of Acute Stroke Management <i>Julie Luker and Kylie Wall</i>	1049
Chapter 43	Analysis of Brain Function using Cerebral Blood Flow Measurements in Patients with Supratentorial Cerebral Strokes <i>Yuzo Araki, Masahiro Furuichi, Hiroaki Nokura and Tasuo Iwata</i>	1065
Chapter 44	The Rehabilitation Function of Motor Imagery after Peripheral Injury or Central Stroke <i>Christian Collet and Aymeric Guillot</i>	1077
Chapter 45	Neuropsychological Issues in Stroke Rehabilitation <i>Robert Ruchinskas and Kelly Blair</i>	1095
Chapter 46	Effects of Walking Speeds and Normalization Methods on the Muscular Activity of the Paretic Lower Limb in Stroke Subjects <i>Luci F. Teixeira-Salmela, Christina DCM Faria, Marie-Hélène Milot and Sylvie Nadeau</i>	1123
Chapter 47	Cardiac Swinging Calcified Amorphous Tumors (SCAT) and Stroke in End-Stage Renal Failure <i>Hiroshi Kubota</i>	1143
Chapter 48	Endovascular Treatment of Acute Ischemic Stroke <i>T. Jonszta, M. Kuliha, M. Roubec, R. Herzig, D. Šaňák, V. Procházka and D. Školoudík</i>	1155
Chapter 49	Metabolic Syndrome, Subclinical Carotid Atherosclerosis and Risk of Stroke: How Strong Is the Link? <i>David Della-Morte and Tatjana Rundek</i>	1195
Chapter 50	Conjugated Linoleic Acids in the Prevention of Ischemic Stroke <i>Yuri Clement</i>	1219

Chapter 51	From Knowledge to Practice: Sustaining Community Engagement in Secondary Stroke Prevention <i>Janet W. H. Sit, Phyllis W. P. Chau, Frankie S. C. Chou and Judy S. H. Lee</i>	1227
-------------------	---	-------------

Chapter 52	Risk of Stroke and Death with Antipsychotics in Dementia Patients <i>Rajesh R. Tampi, Deena Williamson, Vikrant Mittal and Mary Cash</i>	1245
-------------------	---	-------------

VOLUME 6

Chapter 53	Ultrasound in the Management of Ischemic Stroke <i>Narayanaswamy Venketasubramanian and Yohanna Kusuma</i>	1269
-------------------	---	-------------

Chapter 54	Modeling and Optimal Design of Power High Stroke Piezoelectric Actuators for Rotorcraft Applications <i>S. Shevtsov, M. Flek and I. Zhilyaev</i>	1293
-------------------	---	-------------

Chapter 55	Combination Treatment of Repetitive Transcranial Magnetic Stimulation and Intensive Occupational Therapy: A Novel Therapeutic Approach for Upper Limb Hemiparesis After Stroke <i>Wataru Kakuda and Masahiro Abo</i>	1309
-------------------	---	-------------

Chapter 56	Evidence for C-Reactive Protein as A Prognostic Indicator for Ischaemic Stroke Risk <i>Giovanni Corso, Edo Bottacchi and Massimo Veronese Morosini</i>	1327
-------------------	---	-------------

Chapter 57	The Growing Prevalence of Atrial Fibrillation, Especially on Stroke Units <i>João Sargento-Freitas and Luís Cunha</i>	1341
-------------------	--	-------------

Chapter 58	N-Terminal Probrain Natriuretic Peptide as a Biomarker of Cardioembolic Stroke <i>Ana Catarina Fonseca and José M. Ferro</i>	1349
-------------------	---	-------------

Chapter 59	From Cryptogenic Stroke to Paroxysmal Atrial Fibrillation <i>Gustavo Cordeiro, Cristina Duque and Luís Cunha</i>	1359
-------------------	---	-------------

Chapter 60	Novel Oral Anticoagulants for Stroke Prevention in Atrial Fibrillation <i>Vassilis Vassiliou</i>	1375
-------------------	---	-------------

Chapter 61	Stroke in Elderly <i>Mehmet Kolukisa and Talip Asil</i>	1395
-------------------	--	-------------

Chapter 62	Troponin and Acute Stroke <i>Atifur Rahman and Simon A. Broadley</i>	1413
-------------------	---	-------------

Chapter 63	How Could Fluoxetine Exert Therapeutic Effects in Stroke? <i>Virginie Beray-Berthat, Michel Plotkine and Raymond Mongeau</i>	1461
-------------------	---	-------------

Chapter 64	Correlation Between Executive and Motor Function in Patients after Stroke <i>Fadilj Eminović and Slađana Arsić</i>	1483
Chapter 65	Diagnosis and Management of Language Impairment in Acute Stroke <i>Constance Flamand-Roze, Heather Flowers, Emmanuel Roze and Christian Denier</i>	1519
Chapter 66	Socio-Economic Burden of Myocardial Infarction and Stroke Attributed to Road Traffic Noise in Europe <i>Angel M. Dzhambov and Donka D. Dimitrova</i>	1537
Chapter 67	Study of Two Stroke Techniques with Transverse Movement of the Right Hand on Classical Guitar Using Surface EMG <i>Natalia Diaz Fernández de Monge and Juan Granda Vera</i>	1551

VOLUME 7

Chapter 68	Nystagmus in Posterior Fossa Stroke Patients <i>Ksenija Ribarić Jankes, Ljiljana Beslać Bumbaširević, Ivana Berisavac and Višnja Padjen</i>	1565
Chapter 69	Eating Habits, Falls and Stroke Risk <i>Bajram Kamberi and Gojart Kamberi</i>	1577
Chapter 70	Effects of Physical Exercise Following Ischemic Stroke: Is Timing an Important Factor? <i>Fauzia Akbary, Krzysztof Grzegorzcyk and Yuchuan Ding</i>	1593
Chapter 71	Stroke and Traumatic Brain Injury <i>Panagiota Korenis</i>	1619
Chapter 72	Virtual Exercises to Promote Cognitive Recovery in Stroke Patients <i>Pedro Gamito, Jorge Oliveira, Nuno Santos, José Pacheco, Diogo Morais, Tomaz Saraiva, Fábio Soares, Catarina S Mayor, Ana F Barata and Rodrigo Brito</i>	1625
Chapter 73	Automatic Non-Contact Categorization of Upper Body Motion Impairments and Common Post-Stroke Motion Synergies <i>Babak Taati, Jennifer Campos, Jeremy Griffiths, Mona Gridseth and Alex Mihailidis</i>	1635
Chapter 74	Patient Engagement and Clinical Feasibility of Augmented Reflection Technology for Stroke Rehabilitation <i>Simon Hoermann, Leigh Hale, Stanley J Winser and Holger Regenbrecht</i>	1645
Chapter 75	Combining Virtual Reality and a Myoelectric Limb Orthosis to Restore Active Movement after Stroke <i>Sergi Bermúdez i Badia, Ela Lewis and Scott Bleakley</i>	1655

PREFACE

This 9 volume set covers a wide range of topics, including:

- childhood vasculitic stroke
- anosognosia
- stroke-rehabilitation games
- electrical stimulation
- vasculitis

Chapter 1

MANAGEMENT OF CAROTID STENOSIS: CAROTID REVASCULARIZATION IN THE MODERN ERA

Pratik Bhattacharya*

The Detroit Medical Center, Department of Neurology,
Stroke Program, Wayne State University, Detroit, MI, US

ABSTRACT

Carotid artery atherosclerosis is responsible for 10-15% of all supratentorial ischemic strokes. Over the last 2 decades, several clinical trials for carotid revascularization have been conducted, which have influenced our choices of revascularization procedures. Carotid artery stenting, previously regarded as an option for high surgical risk patients only, is now proposed as a reasonably effective and safe alternative to carotid endarterectomy for certain classes of young subjects. The treatment of asymptomatic carotid stenosis is still under debate. Evidence is accumulating that improved medical therapy has led to a lower risk of stroke in medically treated patients with asymptomatic carotid stenosis, than the periprocedural risk from revascularization therapies.

In this review, we will examine carotid revascularization from a historical perspective. We will review data from contemporary clinical trials that have shaped contemporary understanding of the efficacy and safety of Carotid artery Stenting and Endarterectomy. Finally, we will review the evidence supporting intensive medical therapy for asymptomatic patients with carotid stenosis.

ATHEROSCLEROSIS: THE ROLE OF INFLAMMATION

Atherosclerosis, as we currently understand it, is an inflammatory disease. It is a multifocal process, simultaneously affecting various medium and large arterial beds such as

* Corresponding Author's Email: pdhbhatta@med.wayne.edu.

the coronary, cerebral and peripheral arterial vasculature [1]. The endothelium plays a dynamic role in the inflammatory process. Leucocytes and intimal smooth muscle are also actively involved. Inflammation plays a key role, in the initiation, progression and vulnerability of atherosclerotic plaque [1].

Normal endothelium is quiescent. It is in an anti-inflammatory state, with excess production of nitric oxide: regarded protective for the endothelium. Vascular risk factors such as hypertension, diabetes, oxidized low density lipoprotein (LDL) cholesterol, very low density lipoprotein (VLDL) cholesterol, smoking; homocysteine; certain infections and in case of the extracranial carotid artery, mechanical shear stresses in the region of the carotid bulb, convert the anti-inflammatory endothelial cell into a pro-inflammatory state [1]. This is characterized by excess production of oxygen-derived free radicals such as superoxide and peroxynitrites. One of the major effects of oxygen-derived free radicals is the oxidation of LDL cholesterol. Oxidized LDL has a major role in the initiation and propagation of atherosclerotic plaque. It results in activation of other endothelial cells as mentioned above. It induces production of endothelium adhesion molecules, which attract monocytes to the area. Further, it activates monocytes into macrophages, which engulf oxidized LDL molecules resulting in foamy macrophages. Oxidized LDL also reduces the expression of nitric oxide synthase, decreasing the production of protective nitric oxide [1]. Another downstream effect of oxidative stress is the expression of nuclear factor-KappaB (NF-KB). This molecule also results in expression of endothelial cell adhesion molecules, which attract inflammatory cells. It also results in increased expression of matrix metalloproteinase 9: MMP 9 (a molecule that has received considerable interest in the recent years in the field of coronary and cerebral atherosclerosis). The molecule results in deterioration of the extracellular matrix; promoting migration of leukocytes and smooth muscle cells into the sub endothelial area. In the fully developed plaque, MMP 9 may weaken the fibrin cap, resulting in plaque rupture [1].

The American Heart Association has described various stages of atherosclerotic plaque evolution, starting with an initial lesion when macrophages are activated [2]. This progresses to a fatty streak where foamy macrophages are formed. These progress to intermediate lesions where foamy macrophages increase in number, and some of them die resulting in extracellular lipid formation [2]. Up to this stage, plaques are usually asymptomatic. As the extracellular lipid increases in quantity, the plaque is now called an atheroma. This progresses to a fibroatheroma with a defined lipid necrotic core and a fibrous cap [2]. When sufficient amount of necrotic lipid accumulates, it may crystallize into cholesterol crystals [3]. The jagged crystals may cause a rupture of the fibrous cap or may rupture the vasa vasorum of the artery resulting in intraplaque hemorrhage. Such a complicated lesion is the setting for initiation of thrombosis [3]. Once a necrotic lipid core begins to form, the patient is prone to develop clinical symptoms.

EVOLUTION OF CAROTID REVASCLARIZATION

In 1954, a case report of the removal of the stenotic segment of the carotid artery was published [4]. Over the next couple of decades, carotid endarterectomy (CEA) evolved as a method of treatment for carotid stenosis. Up to 1985, two negative randomized trials comparing CEA with medical therapy were published [5, 6]. In spite of negative trials, the

utilization of CEA procedures continued worldwide. Around this time, the EC-IC (External Carotid- Internal Carotid) bypass study for treatment of carotid stenosis was conducted, and the study failed to show benefit [7]. It was in this setting that the NASCET (The North American Symptomatic Carotid Endarterectomy trial) was conceived and eventually began randomization in 1987 [8].

While there have been numerous clinical trials and registries that have shaped our understanding of the treatment of carotid stenosis over the last 25 years, in this discussion, we will concentrate on trials conducted in the United States and those that have provided the most important information.

THE NORTH AMERICAN SYMPTOMATIC CAROTID ENDARTERECTOMY TRIAL (NASCET)

The North American Symptomatic Carotid Endarterectomy trial recruited patients with symptomatic carotid stenosis greater than 30%, and randomized them to medical therapy versus CEA [8]. By 1991, the benefit of the procedure in patients with severe stenosis of 70 to 99% was established [9]. Thereafter, up to the end of recruitment in 1996, only patients with moderate stenosis were randomized. The perioperative stroke and death rate (up to 30 days) in this trial was 6.7% [8]. The average follow-up was 5 years. If patients in the medical arm progressed to greater than 70% stenosis, they were offered CEA.

After an average 24 months follow-up, patients with severe carotid stenosis of 70 to 99% showed a dramatic risk reduction of any ipsilateral stroke from 26% in the medical arm to 9% in the CEA arm. The absolute risk reduction was 17% ($p < 0.001$), which translated to a robust number needed to treat of 6. Among patients with moderate stenosis of 50 to 69%, CEA showed a significant but less robust reduction in risk of any ipsilateral stroke from 22.2% in the medical arm to 15.7% in the CEA arm. The absolute risk reduction was 6.5% ($p = 0.045$), giving a number needed to treat of 15 [8]. Patients with mild stenosis of 30 to 49% did not achieve a significant risk reduction of any ipsilateral stroke following CEA (medical arm 18.7% versus CEA arm 14.9%; absolute risk reduction 3.8% ($p = 0.16$) [8].

The NASCET trial, which completed randomization in 1996, set the paradigm for treatment of patients with moderate to severe symptomatic carotid stenosis. These patients are always treated with a revascularization procedure. Till date, no clinical trials after NASCET have challenged the paradigm of revascularization of symptomatic carotid stenosis. This is in spite of the fact that the comparison medical arm in NASCET would be considered far from adequate in this day and age. Only 16% of patients assigned to the medical arm and 13% of patients assigned to the CEA arm were on lipid lowering medications [8].

IDEAL TIMING FOR REVASCULARIZATION PROCEDURES

Following an ischemic stroke, the highest risk for recurrent stroke is during the first month; the risk decreases with time due to plaque stabilization and the development of collaterals [10]. Presumably, then, the benefit obtained from carotid revascularization for a symptomatic carotid stenosis would decline with time. On the other hand, very early

revascularization procedures could potentially lead to hemodynamic changes within an acutely necrotic area of infarcted brain, resulting in intracerebral hemorrhage [10].

To answer this question, Rothwell et al. reviewed patient data from the NASCET trial and a similar European clinical trial: The European Carotid Surgery Trial (ECST) [11]. This included 5893 patients with 33,000 patient years of follow-up. They reviewed a primary outcome of any stroke or death within 30 days and five-year ipsilateral stroke. Patients with moderate stenosis and severe stenosis showed significant benefits from CEA if the procedure was performed within 2 weeks of the index event. The benefit declined thereafter, and was no longer statistically significant beyond 2 weeks [11]. Based on this data, the American Heart Association recommends that it is reasonable to perform CEA when indicated for patients with stroke or TIA within 2 weeks, rather than delaying surgery [12]. Some contraindications to surgery within 2 weeks could be patients who have very large infarctions at high risk of hemorrhagic conversion, or already have hemorrhagic conversion of their infarctions. In these scenarios it may be prudent to wait beyond 2 weeks.

THE ASYMPTOMATIC CAROTID ARTERY SURGERY TRIAL (ACAS)

The Asymptomatic Carotid Artery Surgery trial recruited patients between 1987 and 1993. The study randomized 1662 asymptomatic patients up to 79 years of age with greater than 60% stenosis to CEA versus medical therapy [13]. In this study, the perioperative stroke and death rate (30 days) was 2.3%. The risk of perioperative stroke and death, and five-year risk of ipsilateral stroke was 11% in the medical arm (the annual risk of ipsilateral stroke in the medical arm was 2.3%) and 5.1% in the CEA arm (p value=0.004) [13]. Thus, there was an absolute risk reduction of 5.9% for the primary outcome by offering CEA. Upon further review of the Kaplan-Meier curves in the study, the CEA curve crossed the medical arm 10 months out from the procedure and a statistically significant benefit of CEA over medical therapy was only seen after 3 years [13]. Thus, in the asymptomatic population the benefit of CEA was less robust and more delayed than noted in the NASCET trial with symptomatic patients.

There were some additional findings of interest in the ACAS study. While the overall relative risk reduction with CEA over medical therapy for asymptomatic carotid stenosis was 57%, there was a sex difference favoring males. The relative risk reduction in males was 66% versus a less impressive 17% among females with asymptomatic stenosis [13]. The benefit of revascularization was greater amongst younger patients less than 68 years: relative risk reduction of 60% versus 43% in patients older than 68 years [13].

THE ASYMPTOMATIC CAROTID SURGERY TRIAL (ACST-1)

A more contemporary trial on patients with asymptomatic carotid stenosis was the Asymptomatic Carotid Surgery trial. Patients were recruited between 1993 and 2003 [14]. In all, 3120 asymptomatic patients were randomized to immediate CEA versus indefinite deferral of CEA (medical therapy). The median follow-up was 9 years, providing an excellent opportunity to study the durability of the results of CEA. In this study, the perioperative risk

of stroke or death was 3%. The study found a significant protective effect of CEA against any stroke or perioperative death at 5 years (10.9% in the deferred arm versus 6.9% in the immediate CEA arm, $p=0.0001$) [14]. This benefit was sustained up to 10 years (17.9% in the deferred arm versus 13.4% in the immediate CEA arm, $p=0.009$) [14].

While the ACST 1 trial showed a durable benefit of CEA in asymptomatic patients, there are certain caveats worthy of note. The intensity of medical therapy evolved significantly over the duration of the trial. The use of antihypertensive therapy improved from 55% to 87% in the medical arm and 51% to 89% in the CEA arm over the 10 years of the study, leading to a decrease in mean diastolic pressures of 6.5 mmHg over the course of the trial [14]. The use of lipid lowering therapies improved from 11% at the start of the trial to 80% by the end of the study in the medical arm and from 7% to 82% in the CEA arm [14]. As the quality and intensity of medical therapy improves over the years, it has become increasingly difficult to justify the use of a revascularization procedure in the asymptomatic population.

STENTING AND ANGIOPLASTY WITH PROTECTION IN PATIENTS AT HIGH RISK FOR ENDARTERECTOMY TRIAL (SAPPHIRE)

The turn of the century saw increasing utilization of angioplasty and carotid artery stenting (CAS) as a carotid revascularization technique. This method provided an attractive alternative for revascularization in the patient who was at high surgical risk. In this setting, Stenting and Angioplasty with Protection in Patients at High Risk for Endarterectomy trial was designed. Between 2000 and 2002, 334 patients (greater than 50% stenosis if symptomatic and greater than 80% stenosis if asymptomatic) were randomized to CEA versus CAS with embolic protection device [15]. The study defined high-risk surgical criteria which included clinically significant cardiac disease (congestive heart failure, abnormal stress test, need for open-heart surgery), severe lung disease, contralateral carotid occlusion, contralateral laryngeal nerve palsy, previous radical neck surgery, previous radiation to the neck, recurrent stenosis after CEA and age greater than 80 years. The trial was powered for noninferiority rather than superiority [15].

The primary outcome of 30 day death, stroke and myocardial infarction (MI) and one year stroke or neurological death was observed in 12.2% of the CAS arm and 20.1% of the CEA arm [15]. This did not reach statistical significance for superiority, but was statistically significant for noninferiority ($p=0.004$). The secondary outcomes: major ipsilateral stroke (0.6% in the CAS arm and 3.3% in the endarterectomy arm), minor ipsilateral stroke (3.7% in the CAS arm and 2.0% in the CEA arm), MI (3.0% with CAS and 7.5% with CEA) were not significantly different in the intention to treat population. However, in the per protocol population, the CAS arm had significantly fewer major strokes (0% versus 3.5%, $p=0.02$) and significantly fewer MIs (2.5% versus 8.1% with CEA, $p=0.03$) [15]. While the primary outcome was not significantly different in the symptomatic subgroup of patients (16.8% with CAS and 16.5% with CEA, $p=0.95$); CAS proved significantly safer with regards to the primary outcome among the asymptomatic subgroup (9.9% with CAS and 21.5% with CEA, $p=0.02$). The study concluded that CAS was noninferior to CEA for high-risk populations for prevention of stroke, death or MI [15].

THE CAROTID REVASCULARIZATION ENDARTERECTOMY VERSUS STENTING TRIAL (CREST)

The studies described in the previous sections laid the ground for the Carotid Revascularization Endarterectomy versus Stenting trial. Most of our current understanding regarding the management of carotid stenosis is based on the findings of this trial. The trial started recruiting symptomatic patients in 2001 [16]. In 2005, recruitment was extended to asymptomatic patients in order to reflect the real-world scenario, where the majority of revascularization procedures are performed amongst asymptomatic patients. Inclusion of asymptomatic patients markedly improved the recruitment rate. The primary outcome was stroke, MI or death during the periprocedural period or any ipsilateral stroke within 4 years.

Interventionalists participating in CREST underwent a rigorous certification procedure. Physicians who did not meet the stringent requirements in terms of experience and complication rates were entered in a “lead in” phase [16]. Physicians were allowed to enter the randomization phase of the trial only after they had successfully completed the lead-in phase. Another feature was the use of predetermined stents and embolus protection devices as well as periprocedural medication dosages. A noteworthy feature about the assessment of outcomes was the regular screening for MIs with EKGs and cardiac enzymes before and after the procedure [16]. Some critics question the inclusion of MI within the primary outcome while evaluating procedures intended for stroke prevention [17].

At the end of 4 years of follow-up, the primary outcome occurred in 7.2% of the 1262 patients in the CAS arm and 6.8% of the 1240 CEA patients, $p=0.51$ [16]. Evaluation of Kaplan-Meier curves suggested no difference in the primary outcome between the procedures throughout the duration of follow-up. However, upon review of the individual components of the outcome, certain significant differences were observed. When compared with the CEA arm, patients in the CAS arm had significantly higher perioperative strokes (4.1% CAS versus 2.3% CEA, $p=0.01$) and perioperative minor ipsilateral strokes (2.9% CAS versus 1.4% CEA, $p=0.009$) [16]. Perioperative MI was significantly higher among the CEA patients (1.1% CAS arm versus 2.3% CEA, $p=0.03$). The significant increase in strokes among the CAS patients was noted up to 4 years (6.2% CAS versus 4.7% CEA, $p=0.049$) [16]. The traditionally accepted outcome of stroke and death in the perioperative period and stroke up to 4 years of follow-up was also significantly higher in the CAS arm (6.4% with CAS and 4.7% with CEA, $p=0.03$) [16]. It appeared that the increased rate of strokes seen with CAS was balanced by increased periprocedural MI with CEA.

As outcomes go, do strokes or MIs have greater impact? The physical component of the SF 36 questionnaire was significantly worse at one year among stroke patients, but showed an uncertain effect among MI patients. The mental component was also significantly worse among stroke patients at one year [16]. On the other hand, mortality rates were more than 3 times higher among patients who suffered an MI in the perioperative period, and also amongst patients who only had elevations of cardiac enzymes. This was true even after adjustment of baseline co-morbid factors. [18]

CAROTID REVASCULARIZATION IN ASYMPTOMATIC PATIENTS

In the CREST study, about 47% of the overall population was asymptomatic [16]. The rate of the primary outcome was similar: 5.6% in the CAS arm and 4.9% in the CEA arm [19]. None of the individual outcomes were significantly different in the asymptomatic subset. It is noteworthy that the stroke and death rate by 4 years was 4.5% in the CAS arm and 2.7% in the endarterectomy arm [19]. While not statistically significant, this difference may be clinically important. CREST was not designed for asymptomatic patients initially. The study methods did not provide enough power to identify significant differences in the asymptomatic subgroup. It is plausible that a similar trial designed with sufficient power in the asymptomatic subgroup would have found the above difference in stroke and death rate to be significant [17].

CAROTID REVASCULARIZATION IN THE ELDERLY

An important finding in the CREST study was an effect modification of the primary outcome by age. Patients older than 70 years of age appeared to do better with CEA, whereas patients younger than 70 years of age fared better with CAS ($p=0.02$ for interaction) [16]. The rate of primary outcome with CEA was 6.1% for subjects younger than 65 years, 6.8% for subjects between 65 to 74 years and 7.4% for subjects 75 years and older [20]. On the other hand, there was a progressive rise in the rate of primary outcome in the CAS arm with age: 3.9% if less than 65 years, 6.3% in the 65 to 74 years age group and 12.7% in patients 75 years and older [20]. Symptomatic status did not modify this effect further i.e., the age-treatment interaction was found in symptomatic and asymptomatic subjects [20].

A similar interaction was also found when the stroke endpoint (periprocedural stroke and post procedure ipsilateral stroke) was examined: 3.7% in patients younger than 65, 5.1% in subjects 65 to 74 years and 10.9% in subject 75 years and older ($p=0.033$ for interaction) [20]. If perioperative stroke and ipsilateral stroke up to 4 years was considered, patients in the CAS arm fared worse than CEA patients if they were over the age of 64 years [20].

The interaction with age was also seen in a meta-analysis of 3 carotid intervention trials: EVA-3S, SPACE and ICSS [21]. The event rate for any stroke or death in the CEA arm was 5.7% in subjects younger than 70 years and 5.9% in subjects 70 years and older. On the other hand, any stroke or death occurred in 5.8% of subjects younger than 70 years in the CAS arm and 12% of subjects 70 years and older [21].

CAPTURE2 is a carotid stent post-marketing registry that recently published results [22]. Out of 5297 patients in the registry 1166 subjects were over the age of 80; only 15% of this group was symptomatic [22]. In other words, close to a fifth of the patients in this registry were elderly and asymptomatic: a demographic with hardly any clinical trial evidence. The 30-day stroke and death rate in the subgroup of patients over 80 years was 4.5% [22]. In the CREST lead in phase, 432/1565 subjects were 75 years and older. The overall 30-day stroke and death rate in subjects over 75 years was 7.5% (5.4% in the asymptomatic group [23]). SAPHIRE WW is another post marketing registry where 520 out of the reported 2001 patients were over the age of 80 years. These elderly patients had nearly twice the rate of 30-day stroke and death compared to patients below the age of 80 years (OR: 1.92) [24]. While

these data suggest that CAS in the elderly have high rates of 30-day stroke and death; we have very little clinical trial data of complication rates from CEA or medical therapy in this subgroup. The ACST-1 study had 30/1662 patients in the CEA arm who were over the age of 75 years, and 38/1701 subjects in the medical arm over the age of 75 years [14]. Within this subgroup of elderly patients in ACST 1, medical therapy achieved equivalent results to revascularization by CEA (OR: 0.81, 95% CI 0.43-1.51) [14].

CAROTID REVASCULARIZATION IN WOMEN

Across most carotid revascularization trials, women tend to carry more perioperative risk than men. The smaller diameter of the carotid artery in women compared to men is the presumed cause for this phenomenon [25]. Gender wise differences in perioperative risk from carotid revascularization in the CREST study have been published. The rate of 30-day stroke, death or MI in the CAS arm was 4.3% amongst men and 6.8% amongst women [26]. This complication rate with CAS was not significantly different than CEA in men (4.9%); but the rate in women was significantly higher in the CAS arm compared with the CEA arm (3.8%, $p=0.047$) [26]. Among women, the 30-day stroke and death rate in the CAS group was 5.5%, and 2.2% in the CEA group, $p=0.013$ [26]. CAS amongst the symptomatic women also resulted in a significantly higher 30-day stroke and death rate compared to CEA (7.5% versus 2.7%, $p=0.03$). In the asymptomatic women, CAS had a higher, albeit nonsignificant rate of 30-day stroke and death compared to endarterectomy (3.3% versus 1.6%, $p=0.28$) [26].

The author reviewed contemporary in-hospital stroke and death rates following carotid CAS within his own institution. Between June 2009 and May 2011, 483 carotid revascularizations were performed, out of which 307 (63.6%) were carotid stents. The in-hospital stroke and death rate was higher amongst women than men (4.4% versus 1.6%). In asymptomatic women, the in-hospital stroke and death rate was 4.5%-note that the nationwide benchmark for 30-day stroke and death rate is less than 3%. In the subset of women who were asymptomatic and over the age of 70 years, the in-hospital stroke and death rate was 6.1%.

PHYSICIAN SPECIALTY AND THE CHOICE OF REVASCULARIZATION PROCEDURE

At the author's own institution, review of contemporary data revealed that 87% of CAS were performed by cardiologists [27]. In spite of the age interaction demonstrated in CREST, where patients older than 70 years fared worse with CAS, 50.3% of patients receiving carotid artery stents after the announcement of the CREST results were 70 years old and above. In fact, following CREST, a significant increase in the proportion of procedures performed for nonspecific neurological symptoms such as lightheadedness or dizziness was noted (5.5% of procedures before CREST versus 18.3% of procedures after CREST, $p=0.002$) [27]. Presumably, the elderly are more likely to have nonspecific symptoms, for which they may receive a carotid duplex screen by their internists. Detection of a carotid stenosis in this manner may prompt a cardiology referral for CAS, as internists may believe it to be a less invasive procedure. Elderly patients are also more likely to have cardiac disease, and be

evaluated by cardiologists, who may screen the carotid vessels during evaluation of the coronary vasculature, picking up asymptomatic stenoses.

These theories of the role of physician specialty in the selection of carotid revascularization procedures were tested in a study on Medicare beneficiaries between 2005 and 2007 [28]. Among all specialties performing CAS, utilization of the procedure increased the most among cardiologists. Cardiologists comprised one third of all operators, but performed 52% of all carotid stents [28]. The patients who received stents from cardiologists were more likely to have higher rates of invasive cardiac procedures and were more likely to be asymptomatic (bearing out the aforementioned theories). In this study, 30-day outcomes did not vary by specialty [28].

CAROTID CAS COMPLICATION RATES OVER TIME

As technology advances, improvements in techniques and skill may result in lower perioperative complication rates with CAS. Published data from carotid artery standing post-marketing registries over the last decade appear to suggest this phenomenon [29]. Within the CREST study however, the perioperative stroke and death rates remained steady between 2000 and 2008 [30]. Over time, in CREST, the proportion of asymptomatic patients progressively increased and the proportion of elderly patients over the age of 80 years progressively decreased. Even after adjustment for symptomatic status and age, the perioperative stroke and death rates did not change over time in CREST [30].

A similar finding was demonstrated in the analysis of in-hospital complications following CAS in the Nationwide Inpatient Sample [31]. The trend of in-hospital stroke, death or MI did not change between 2004 and 2009. Trends were examined for asymptomatic and symptomatic patients, males and females, elderly patients 80 years and older as well as younger patients below the age of 80 years. Complication rates did not trend downward in any of these subgroups.

MAKING THE CASE FOR INTENSIVE MEDICAL THERAPY FOR ASYMPTOMATIC CAROTID STENOSIS

Spence et al. have demonstrated the efficacy of a new treatment paradigm instituted in their population since 2003 [32]. In this paradigm, carotid plaque area is monitored. Medical therapy including lifestyle changes, lipid management, blood pressure control and use of medications for insulin resistance is progressively intensified upon increases in plaque area. Using such intense medical therapy, they were able to significantly lower the rates of stroke, death and MI. The authors in that study also followed patients with transcranial Doppler monitoring for micro emboli. They demonstrated a significant drop in percentage of patients with micro emboli following the institution of the new paradigm of intensive medical therapy [32]. The authors also demonstrated a significantly higher rate of stroke, death and MI among patients with micro emboli in comparison with those without micro emboli [32]. Transcranial Doppler may prove to be an important tool to identify patients with asymptomatic carotid

stenosis who are at a higher risk of vascular events. In other words, micro emboli may serve as a useful biomarker of vulnerable carotid plaque.

Anne Abbott reported a meta-analysis of 11 asymptomatic carotid intervention studies between 1985 and 2007 [33]. She used raw data from these trials to calculate rates of ipsilateral stroke, ipsilateral stroke/TIA, any territory stroke and any territory stroke/TIA in the medical therapy arm. There was a significant reduction in the rate of each outcome over the years [33]. The outcome rates in the more contemporary studies were quite similar, if not better than the CEA arm in the ACAS trial [33]. Considering the extremely low stroke rate achieved by intensive medical therapy among patients with asymptomatic carotid stenosis, the benchmark of 3% perioperative stroke or death from revascularization procedures set by the American Heart Association seems generous and may have to be reduced further.

FUTURE DIRECTIONS

Two clinical trials are currently randomizing patients with asymptomatic carotid stenosis to CAS versus CEA. ACT-1 (the Asymptomatic Carotid trial) is randomizing asymptomatic patients at standard risk for surgery. CAS procedures in this class of patients are not reimbursed currently in the United States. The ACST-2 (Asymptomatic Carotid Surgery trial-2) is randomizing standard and high risk patients with asymptomatic stenosis to CEA versus CAS. In view of the extremely low event rates noted with contemporary medical therapy among asymptomatic patients, a carotid intervention study with a medical arm for asymptomatic patients is being planned and currently awaits funding.

ABSTRACT

Ischemic stroke (IS) is due to the sudden occlusion of a cerebral artery with the consequence of a critical reduction in cerebral blood flow in a localized region (rCBF) of the brain. It represents the second cause of death and the leading cause of neurological disability in developed countries. Primarily due to the resulting economic burden, IS is considered a world-wide challenge. Different strategies can be identified to face this challenge: acute treatment, primary and secondary prevention, rehabilitation.

For several years acute IS treatment has been based on the use of the only current drug approved in the first 3 hours from symptom onset: recombinant tissue plasminogen activator (rtPA). However, mainly due to the short therapeutic window, a low percentage of patients can be actually treated by rtPA. Thus, with improving diffusion of more accurate diagnostic tools and of prognostic informations in different clinical scenarios, new treatment strategies in the acute phase have been developed such as intra-arterial and mechanical thrombolysis.

Prevention plays a crucial role in counteracting the economic burden of IS through life-style changes, vascular risk factors control (with arterial hypertension being the main one for IS) and antiplatelet therapy. Moreover prevention therapy has been enriched by the introduction, in the last few years, of new drugs with pleiotropic effects such as statins and ACE-inhibitors. Also potential pleiotropic effects of antidiabetic drugs are currently under investigation. New insights in secondary prevention come from the use of phosphodiesterase inhibitors such as dipyridamole (in combination with aspirine) and cilostazol. The latter demonstrated to be more effective than aspirin in reducing the risk

of recurrent stroke with the advantage of dramatically reducing the risk of haemorrhagic events as compared to aspirin.

Rehabilitation strategies are weighted, together with acute IS treatment, by most of stroke physicians and patients expectations. Among them transcranial magnetic stimulation (TMS) is a new tool able to explore and affect critical aspects of neural plasticity, thus being of great importance in the understanding and treatment of those fundamental functional recovery mechanisms triggered after stroke.

The present chapter will focus on standard, current and new potential treatments of acute phase, prevention and rehabilitation of IS.

INTRODUCTION

Ischemic stroke (IS) is the consequence of a critical reduction of cerebral blood flow in a localized brain region resulting from the sudden occlusion or progressive narrowing of a large or small cerebral artery [1]. The result is the definitive (IS) or temporary (transient ischemic attack or TIA) loss of function of the affected region in the brain with consequent appearing of neurological deficits such as facial drop, slurred speech, speech arrest, weakness of the arm and / or leg on the same side.

It is estimated that 530000 people experience a new IS each year in the USA and on average every 40 seconds someone in the same country has a stroke [2]. In terms of mortality stroke ranks number 4 among all cause of death after heart disease, cancer and chronic lower respiratory disease [3]. However it remains the first cause of adult neurological disability in developed countries [4]. About 80% of patients come back home but about half of them needs permanent or temporary help in the home setting [5]. In fact with improvement of treatment strategies, more patients survive so that the annual stroke rate decreased 34.3% from 1997 to 2007 and actually 18.8%. Unfortunately many of stroke patients remain with physical and cognitive sequelae with consequent increased personal and public costs [2,5]. In this regard, a recent estimation of the total direct (cost of physicians and other professionals, hospital services, prescribed medications, home health care) and indirect (lost of productivity/mortality) costs deriving from stroke resulted in about 41 billions of dollars with an overall cost for all cardiovascular diseases estimated to be about 286 billions of dollars [6].

Data from the Framingham Heart Study showed that stroke incidence is declining over time: in particular the age-adjusted incidence of first stroke per 1000 person-years has decreased from 7.6 for men and 6.2 for women in the period 1950-1977 to 6.2 for men and 5.1 for women in the period 1990-2004 [7].

However, a recent systematic review showed over the past four decades a 42% decrease in stroke incidence in high income countries and a greater than 100% increase in stroke incidence in low-to-middle income countries [8]. On the contrary, stroke severity did not vary across these periods [7]. The risk of first-ever stroke in blacks is almost twice than in whites and this racial disparity doesn't seem to change over time. Socioeconomic condition has been hypothesized to be implicated in the excess stroke incidence in blacks [9].

Among stroke risk factors, TIA confers an important short-term risk of stroke (10% within 90 days and 5% within 2 days) [10]; hypertension plays a crucial role in the risk of both ischemic stroke and intracranial hemorrhage [11]. Diabetes mellitus nearly triples while current cigarette smoking doubles this risk [12]. Atrial fibrillation, although often asymptomatic and undetected, is an important risk factor for stroke, increasing stroke risk

about 5-fold throughout all ages so that its relevance could be underestimated [13,14]. Patients with low concentrations of HDL cholesterol have been found to be at higher risk of stroke [15]. Further depressive symptoms have been increasingly recognized as a risk factor (4-fold higher) for stroke/TIA [16]. Clinical and experimental research are aimed at counteracting the global impact of IS in terms of economic and disability burden. Over the last decades, three different aspects of IS management have been deeply investigated: primary and secondary prevention, acute treatment and rehabilitation. The present chapter will focus on each one of the aforementioned phases of IS management, highlighting all current recommended procedures and potential new developments.

ACUTE ISCHEMIC STROKE TREATMENT

IS includes a region characterized by a decrease in blood flow below the threshold of energy failure which is called ischemic core and a surrounding area called ischemic penumbra (IP) (figure 1). The latter has been regarded as a region in which reduction in blood flow goes under the threshold for failure in electric function but not for membrane failure. The main concept deriving from this assumption is that the tissue in this region is still viable [1,17].

Cerebral blood flow studies based on magnetic resonance imaging (MRI) and positron emission tomography (PET) have shown that the IP represents a potentially reversibly damaged tissue, while its conversion to complete infarction is responsible for acute clinical deterioration in stroke patients [1,18]. For the same reason IP represents the main target of acute IS treatment whose purpose is therefore to reduce the amount of IP that can become irreversibly damaged thus enlarging the IC.

Figure 1. Schematic representation of blood supply to the penumbral tissue through leptomeningeal anastomoses (LMA). ACA: anterior cerebral artery; MCA: middle cerebral artery; PCA: posterior cerebral artery.

Up to now, the only drug authorized for the acute stroke treatment is a thrombolytic agent called recombinant tissue plasminogen activator (rtPA) administered intravenously (I.V.) within 3 hours of symptom onset. Endogenous tPA is a serine protease (found in endothelial cells) that catalyzes the conversion of plasminogen to plasmin. The latter is responsible for conversion of fibrin clot in fibrin degradation products and clot breakdown [19]. Compared to the first generation plasminogen activators (streptokinase and urokinase), rtPA has a higher affinity for fibrin and is activated by fibrin with consequent activation of plasminogen on the fibrin surface. Thus due to this fibrin specificity, rtPA is able to induce effective thrombolysis without enhancing systemic plasma proteolysis [20,21]. Therefore, the aim of thrombolytic therapy is to lyse an occluding thrombus or embolus, to restore function in potentially still-viable tissue and to reduce the volume of cerebral tissue irreversibly damaged.

The trigger for the Food and Drug Administration (FDA) approval of rtPA in acute stroke treatment in 1996 came from the results of the National Institutes of Neurological Disorders and Stroke (NINDS) Trial (1995) which demonstrated that i.v. administration of rtPA at a dosage of 0.9 mg per kilogram of body weight (10% bolus and resting dose in 1 hour) was able to increase the number of patients with good clinical outcome as compared with the untreated group [22]. In particular, treated patients were at least 30 percent more likely to have minimal or no disability at 3 months, and this effect was confirmed at 1 year follow-up [23].

However, contrary to its successful employment in acute myocardial infarction, one of the main complications of thrombolysis in stroke is intracerebral haemorrhage (ICH) which can offset any beneficial effects [24]. This complication, together with the difficulty to start treatment within three hours of symptom onset, led to a general criticism about this approach. Further, the NINDS trial was the first and only randomized-controlled trial assessing the usefulness of a thrombolytic agent in acute stroke treatment showing positive results. For all these uncertainties, approval of the European Agency for the evaluation of medical product (EMA) came only in 2002 under condition that i.v. thrombolysis was only used in observational studies and that a new randomized placebo controlled trial was started to evaluate safety and efficacy of i.v. rtPA in the 3-4,5 hours time window. In the following years the Safe Implementation of Treatments in Stroke Monitoring Study (SITS-MOST) registry [26] with 6,483 patients treated with rtPA within 3 hours of symptom onset, confirmed the NINDS results. Other large studies such as the Alteplase Thrombolysis for Acute Non Interventional Therapy in Ischemic Stroke (ATLANTIS) and the European Cooperative Acute Stroke Study (ECASS) further reported the beneficial effects of iv thrombolysis within 3 hours of symptom onset [27,28].

A the short therapeutic time-window is considered the principal responsible of the low (<5%) percentage of treated patients [29]. Many efforts have been made to enlarge the therapeutic time-window. In 2004 a metanalysis of the ATLANTIS, ECASS and NINDS trials [30] investigated the relationship between onset-to-treatment time (OTT) and both favorable 3-month outcome and occurrence of symptomatic ICH (sICH). With 2,775 patients randomly assigned to rtPA or placebo within 360 min of stroke onset, this analysis showed that odds of favorable 3-month outcome increased as OTT decreased with some benefits also beyond the 3-hour window; however the hazard ratio for death was similar for different intervals between 0-270 min while increased in the 271-360 min interval, indicating that, although the potential benefit of rtPA beyond 3 hours, this potential could come with some risks (figure 2).

Figure 2. The relationship between onset-to-treatment time and odds ratio of favorable outcome.

Haemorrhagic complications were seen in 5.9% of rtPA patients and 1.1% of controls and was associated with rtPA treatment and age but not with OTT. In light of this analysis and as requested by the EMEA, in 2008 the ECASS III investigators published the results of a large randomized controlled trial aiming to evaluate safety and efficacy of rtPA administered between 3 and 4.5 hours after the onset of stroke [31]. 821 patients were enrolled and randomly assigned to rtPA group (418) and to the placebo group (403).

More patients had a favorable outcome with rtPA than with placebo (52.4% vs 45.2%; $p=0.04$) and the outcome was also better with rtPA than with placebo. The incidence of ICH (either any or symptomatic ones) was higher with rtPA than with placebo, while mortality did not differ between the two groups. In the same year, another large study called the Echoplanar Imaging Thrombolytic Evaluation Trial (EPITHET) [32] aimed to evaluate whether alteplase, administered between 3 and 6 hours after stroke onset, was able to promote reperfusion and to attenuate infarct growth in patients with demonstrated “still savable tissue” (IP) on MRI. 101 patients were randomized to Alteplase or placebo. The study showed that Alteplase was non-significantly associated with lower infarct growth (calculated on MRI) and with significant reperfusion in patients with demonstrated IP and that reperfusion was associated with better clinical outcome.

Therefore an updated metanalysis, adding data from recent EPITHET and ECASS III trials to those of ATLANTIS, ECASS and NINDS, re-examined the effects of OTT on benefits and risks of Alteplase administration [33]. With 3,670 patients, the analysis confirmed that patients benefit from i.v. rtPA up to 4.5 hours and that sooner the treatment was started, the greater the benefit, especially within 90 minutes. Again, the study showed that beyond the 4.5 hours, the risk could outweigh benefit. Despite all these studies and the supposed improvement in the rate of patients undergoing i.v. thrombolysis as a consequence of widened therapeutic window, a recent study [34] reported that of 1,838 patients only 3.4% arrived in the expanded time interval compared with the 22% arrived in the standard time window. Moreover, only 0.5% from the expanded time frame met eligibility criteria for thrombolysis compared to 5.9% in the standard time frame. Hence, only few patients seem to benefit from the results of ECASS III trial and problems other than the short time therapeutic

window are likely involved in the low rtPA administration rate such as: poor stroke awareness and impaired transport to facilities with ability to administer Alteplase and poor familiarity of physicians with acute stroke treatment guidelines. A way to improve the rate of rtPA administration has been explored in a study which took into account that many contraindications included in the license of Alteplase are not based on scientific evidence, while they restrict significantly the portion of patients with acute IS eligible for treatment with Alteplase [35]. The authors tested whether off-label thrombolysis (patients treated out of license indications for Alteplase) was associated with poorer outcome or increased rate of sICH compared with on-label use (patients from the large randomized controlled trials). They found that more than 50% of treated patients had contraindications to thrombolysis and that off-label treatment was neither associated with poorer outcome (except for age > 80 years), nor with increased rate of sICH when compared with on-label patients. Some innovative aspects have to be taken into consideration from this study in order to find out strategies to overcome the low rate of rtPA administration: 1. more than 10% of patients with minor stroke (a contraindication for the license of Alteplase) were treated thus improving definitely the rate of i.v. thrombolysis treated patients; 2. in order to shorten as much as possible the OTT, there was no reason to wait for laboratory results unless an history or clear clinical sign suggestive of those laboratory abnormalities considered as a contraindication for treatment [35].

From all these data come the needs to start i.v. thrombolysis as soon as possible since “time lost is brain lost”. In this view, in order to enhance and expedite acute stroke care, an important support has been telemedicine [36]. Telemedicine represents a technology which allows the remote interaction and exchange of audio-visual information between physicians at different places [37]. Because of a shortage of stroke specialists, this technology carries the potential of allowing many outlying or “spoke” hospitals to initiate thrombolytic treatment before transferring patients to a regional stroke center hub thus avoiding harmful delay [36]. One of the largest study testing safety and efficacy of telemedicine in stroke, also called telestroke, comes from Germany and in particular from the rural area of Bavaria with its telestroke network composed of 2 stroke centers and 12 local hospitals [38]. The authors designed the study considering that: long distances in rural area may prevent timely admission to the hub; from the German Registers Study Group thrombolysis in local hospitals resulted in increased complication rates [39]; international guidelines suggest that rtPA should only be given if stroke diagnosis is made by a physician with expertise in stroke [40]. Based on this assumption, the authors found a marked increase in the rate of treated patients in local hospitals and a rate of sICH and in-hospital mortality lower than that reported in inexperienced regional hospitals [38].

In the past few years many efforts have been made to evaluate the economics of treating acute IS. This is due to the relevance of stroke as a cause of long-term disability. In the years next to the Alteplase approval it was observed that acute costs of hospitalization and thrombolysis were offset by the greater likelihood of a favorable recovery and thereby a decrease in rehabilitation costs with a net cost savings to the healthcare system [41]. Despite the initial enthusiasm, a discouragement came with the recognition that only 2% of stroke patients were actually treated with rtPA. However, in the last few years, a net increase in the proportion of patients receiving Alteplase has been observed probably due also to the establishment of stroke networks (hub and spoke) and of telestroke [42]. Finally, economics of acute IS treatment proposed that the higher the rtPA administration rate the more remarkable the cost saving. It goes parallel to this concept the relevance of starting treatment

as soon as possible since, as already described, the earlier the treatment the higher the likelihood of good clinical outcome and reduced rehabilitation costs [33,41].

One of the biggest shortcoming of i.v. thrombolysis is the poor outcome obtained in patients with IS secondary to large intracranial arteries occlusion [43,44]. In particular a recent study [45] evaluated the association between the clot location in the intracranial arteries and the likelihood of good clinical outcome after i.v. thrombolysis and found that outcome improved and mortality decreased when moving from proximal (internal carotid artery) to more distal vessel (distal segments of middle cerebral artery) position and that a cut-point between the proximal and distal part of the middle cerebral artery was associated with the largest increase in odds for favorable outcome. The poor outcome, together with the need of extending the therapeutic window, has been the trigger for research in other recanalization strategies. Endovascular therapy represents a current challenge in the treatment of acute IS in the last few years despite devices, specifically designed for this purpose, were first developed in the 1990s and intra-arterial thrombolysis has been used for nearly three decades [46]. The latter has been evaluated in only one randomized trial called Prolyse in Acute Cerebral Thromboembolism II (PROACT II) testing safety and efficacy of this therapy⁴⁷. Patients were randomized to intra-arterial prourokinase with i.v. heparin versus i.v. heparin alone. This trial showed a 66% rate of recanalization and a 40% good neurological outcome. Nowadays these results remain the yardstick by which newer interventional strategies are judged. However, in a meta-analysis of randomized controlled trials evaluating intra-arterial fibrinolysis for acute IS, PROACT II was the only to show a statistically significant clinical benefit but resulted in a net discrepancy between recanalization of occluded cerebral arteries and clinical outcomes since the first had a rate 3 times higher than that of favorable outcome [48]. Moreover prourokinase is no longer available and intra-arterial fibrinolysis is an off-label application of any available fibrinolytic agent since it requires further investigation for on-label application [46,47]. Driven by the knowledge that recanalization (therapeutic or spontaneous) and reperfusion in acute IS are associated with improved outcome and reduced mortality [49], alternative endovascular methods have been investigated such as mechanical thrombectomy. All the devices designed for this strategy offer potential advantages such as more rapid recanalization, ability in recanalization of large-artery occlusions, reduced use of pharmacological thrombolysis with lower risk of ICH and extended therapeutic time-window compared with i.v. thrombolysis [50]. Five kind of neurothrombectomy devices exist: clot retrievers, aspiration or suction devices, snare-like devices, ultrasonography technologies, lasers. Potential harms include direct trauma to the vasculature (vasospasm, dissection, perforation, rupture) and thrombi fragmentation into previously unaffected vessels [51]. Another risk of the procedure itself is represented by the frequent need for intubation and heavy sedation which have been shown to be associated with worse outcome [52]. In particular, a recent retrospective analysis correlated general anesthesia with lower systolic blood pressure values and identified local anesthesia and systolic blood pressure greater than 140 mmHg as independent predictors of good clinical outcome [53]. Currently, only two devices are cleared by the FDA:

1. the Mechanical Embolus Removal in Cerebral Ischemia (MERCII) which is a clot retriever and was the first to be cleared and evaluated;
2. the Penumbra System (PS) which is an aspiration device [54].

Both them have the indication to recanalize the artery within 8 hours of symptom onset. By crossing the site of occlusion, the MERCI retriever pulls the embolus into an extracranial guide catheter under active suction [46] (Figure 3). This device has been tested in 3 prospective, single-arm, nonrandomized studies enrolling patients ineligible for or non-responding to i.v. thrombolysis within 8 hours of stroke onset. Primary outcome included partial or complete recanalization and safety while secondary outcomes included clinical outcome at 30 and 90 days. The studies showed a rate of successful recanalization of 46% that was significantly higher than that expected by using the control arm of the PROACT II (18%) and a rate of good neurological outcomes of 28%; moreover recanalization was associated with good outcome whereas increased age and stroke severity with poor outcome and death [55]. In particular a pooled analysis of the MERCI and multi-MERCI trials highlighted a marked increase in the rate of good clinical outcome in patients with arterial recanalization as compared to the non-recanalized group, identifying internal carotid artery recanalization as a significant predictor of good-90-day outcome and failure in recanalization as a significant predictor of mortality at 90 days [56-58]. In all these studies rates of successful recanalization ranged between 43% and 78%. The PS acts on the proximal face of the clot without crossing it and is used in combination with an aspiration device to debulk and extract the clot (Figure 4). It has been tested in the Penumbra Pivotal Stroke Trial [59] which was a prospective, single-arm, multicenter study that showed a further increase in the rate of successful recanalization (81.6%) compared with the previous trials [59].

Figure 3. Merci retriever.

Figure 4. Penumbra System.

Figure 5. Solitaire device.

Yet, the rate of good clinical outcome was only 25%. Further increase in successful recanalization rate has been observed in a recent study [60] evaluating safety and efficacy of a new device called Solitaire. This is a self-expanding stent that can be fully deployed and then retrieved thus allowing mechanical embolectomy (Figure 5). The authors described impressive results with a rate of successful recanalization of 88% and a rate of favorable outcome of 70% for MCA occlusion, 44% for ICA occlusion and 43% for basilar artery occlusion with an overall rate of 54%. Finally, the overall mortality rate was 12%. Due to its technical characteristics, some risks linked to the use of Solitaire could be the dissection of distal branches and distal dislocation of the clot during the thrombus retrieval.

Although promising results are coming from research in endovascular therapy, mortality rate in treated patients remains around 35% [46]. As already described, some predictors of unsuccessful recanalization have to be taken into account such as poor collateral cerebral circulation, high pre-treatment stroke severity, age > 70 years and elevated clot burden [61,62]. Thus, uncertainty remains about which kind of patient population is the most likely to respond to endovascular therapy. Therefore, a careful patient selection probably based on advanced imaging techniques able to quantify the ischemic core and the ischemic penumbra as well as to evaluate collateral circulation, should be considered for future trials. In our opinion, since successful recanalization seems to correlate with favorable neurological

outcome, the combination of all endovascular strategies currently available should be taken into consideration, at least until results of ongoing and future trials will clarify the superiority of one strategy on another.

FUTURE DIRECTIONS AND CONCLUSION

IS represents an increasing economic burden. Prevention of disability seems to be the way of counteracting healthcare costs through a reduction in disability and associated long-term care costs [63]. Endovascular therapy seems to be a further step, after i.v. thrombolysis, in that direction since its potentials should be to widen temporal therapeutic window beyond 4,5 hours and to achieve a more rapid recanalization, thus increasing the number of treated patients. In this regard training of interventional specialists represents a big challenge since success is directly related to the time of recanalization [64]. However, some authors have recently underlined the lack of relationship between the grade of recanalization and the functional outcome obtained with endovascular therapy, while others have supported the importance of a good pre-treatment collateral flow as an independent predictor of good clinical outcome [61,65]. These authors reported also a higher frequency of infarct growth and of symptomatic haemorrhagic transformation in patients with poor collaterals and achieved recanalization, thus supporting the prognostic value of collateral flow [61]. It has been shown that collateral flow can sustain brain tissue for hours after arterial occlusion and maintenance or potentiation of collateral flow could be regarded as a potential therapeutic target [66,67]. In our opinion some technologies/strategies should be considered worthy of attention in the modulation of collateral flow in the acute phase of ischemic stroke. One of these is repetitive transcranial magnetic stimulation (rTMS) which demonstrated to improve cerebrovascular reactivity (CVR), a marker of perfusion autoregulation ability, in healthy volunteers as demonstrated by our group [68]. Although currently insufficient data exist on the safety and efficacy of statins in acute IS in humans [69], their helpful effect in this specific scenario could be favored by their fibrinolytic action, endogenous nitric oxide synthase (eNOS) upregulation (with increased NO production and consequent potentiation of CVR), increased cerebral blood flow and platelet deactivation [67]. As well as statins, some phosphodiesterase inhibitors such as sildenafil and cilostazol have shown the ability to improve CVR [70,71], to promote angiogenesis, endothelial function and antiplatelet effects thus presenting potentials in the modulation of collateral flow in the early phase of IS [67]. We argue and emphasize our point of view that the need for early recanalization in acute IS has to be considered as a valid reason for combination of all current available strategies with demonstrated success in arterial recanalization, as it has already been elaborated in the design of the Interventional Management of Stroke Phase III trial [72].

STROKE PREVENTION: MANAGING MODIFIABLE RISK FACTORS

Prevention plays a crucial role in counteracting morbidity and mortality related to IS. It has been estimated that 50% of stroke are preventable through control of modifiable risk factors and life-style changes. Stroke Prevention has been recently set as one of the priorities

by an international community of leaders involved in this field) [73], and the American Heart Association (AHA) and American Stroke Association (ASA) have recently published updated guidelines for recurrent stroke prevention [74]. Over the last four decades several certainties have been achieved. Primary prevention strategies that work in primary prevention of IS are: treating hypertension (HTN), and using statins and angiotensin-converting enzyme inhibitors (ACEIs). Attention to lifestyle factors is routinely warranted in both primary and secondary IS prevention: aerobic exercise to counteract inactivity, weight loss in obesity, glucose control in diabetics, smoking cessation, and diet. Patients who have had an IS or transient ischemic attack (TIA) are at high risk for recurrent stroke.

Antihypertensive treatment is recommended for both prevention of recurrent stroke and other vascular events. Cholesterol lowering with statins, and antiplatelets have been shown to reduce the risk of recurrent stroke and other vascular events; ACEIs or Angiotensin II receptor blockers (ARBs) are indicated in stroke prevention because they promote vascular health; effective secondary-prevention strategies for selected patients include carotid revascularization for high-grade carotid stenosis and vitamin K antagonist (i.e., warfarin) treatment for atrial fibrillation. Among potentially modifiable risk factors, consensus does not exist on the role of treating, among others, hyperhomocysteinemia, coagulation disorders, patent foramen ovale, metabolic syndrome, lipoprotein(a), and markers of inflammation to prevent stroke. The results of recent clinical trials investigating new anticoagulants (factor Xa inhibitors and direct thrombin inhibitors) clearly indicate alternative strategies in stroke prevention for patients with atrial fibrillation. Interesting data on the phosphodiesterase inhibitors cilostazol are emerging and need confirmation in randomized controlled studies (RCTs). This review describes the current landscape and developments in stroke prevention with special reference to medical treatment in secondary IS prevention.

TREATMENT OF HYPERTENSION

Arterial hypertension (HTN) is the single most important modifiable risk factor for stroke. HTN contributes to 60% of all strokes (through the following mechanisms: atheroma in carotids, vertebral arteries and aortic arch; friability of small cerebral arteries; left ventricular dysfunction and atrial fibrillation). There is a close, continuous and approximately linear relationship between blood pressure (BP) levels and primary incidence of stroke in both hypertensive and normotensive populations. A 5-year reduction of 5-6 mmHg diastolic blood pressure (DBP) (with mainly diuretics and beta-blockers) has been associated with a 42% relative risk reduction (RRR) of first stroke [75]. Randomized trials on primary stroke prevention in middle-aged and elderly populations confirmed that treating HTN reduces the incidence of stroke. Two placebo-controlled trials (the first using chlorthalidone and atenolol, the second using nitrendipine, with the possible addition of enalapril and hydrochlorothiazide) have demonstrated 36% [76]. and 42% [77] RRR for first ischemic stroke in treating systolic blood pressure (SBP) as compared to placebo. More recently, the LIFE study [78] compared losartan-based regimen versus atenolol-based regimen in 9,193 hypertensive patients with a mean follow-up of 4.8 years. While comparable reductions in BP were observed, losartan treatment was associated with a significant 25% risk reduction versus atenolol of fatal and non fatal stroke. Losartan was better tolerated and seemed to confer benefits beyond reduction

in BP. A recent analysis of RCTs compared first-line calcium channel blockers (CCBs) with other antihypertensive classes, in order to determine whether CCBs reduced the incidence of major adverse cardiovascular events compared to the other antihypertensive classes [79]. Eighteen RCTs, with at least 100 randomized hypertensive participants and with a follow-up of at least two years, with a total of 141,807 participants, were included. Although some results were not enough robust to change practice, CCBs reduced stroke as compared to beta-blockers, ACEIs, and ARBs. However, diuretics were the preferred first-line treatment over CCBs to optimize reduction of cardiovascular events and congestive heart failure.

Few trials have focused on antihypertensive therapy for prevention of recurrent stroke. Two studies using ACEIs have demonstrated that, for patients with hypertension, effective control of BP reduces the risk of recurrent stroke. The Perindopril Protection against Recurrent Stroke Study (PROGRESS) [80] was started in 1996 to answer this question. In this study, about 6,000 hypertensive patients with a prior TIA or stroke in the last 5 years were randomized to receive aggressive HTN treatment (perindopril 4 mg±indapamide 2.5 mg) versus usual care (1 drug) or placebo (1 or 2 placebo). Patients were followed up for 4 years, and the primary outcome was total strokes. Aggressive treatment was associated with a 43% RRR in stroke risk versus usual care (mean BP reduction was 12/5 and 5/3 mmHg). The HOPE trial [81] was a RCT, with 267 participating hospitals in 19 countries. There were 9,297 patients with vascular disease or diabetes plus an additional risk factor, followed-up for 4.5 years (11% of them had prior TIA or IS). Patients were randomized to receive ramipril 10 mg versus placebo. The rate of stroke and TIA were assessed. Reduction in BP was modest (3.8 SBP and 2.8 DBP). The RRR for any stroke was 32%, and the RRR of fatal stroke was 61% (17 versus 44 events) favoring ramipril. Benefits were consistent across patients' subgroups.

More recently, other trials have tested safety and efficacy of ARBs, when used alone or in combination with an ACEI, in preventing stroke recurrence in high-risk populations. In the PReventiOn regimen For Effectively avoiding Second Strokes (PROFESS) trial [82], 20,332 ischemic stroke patients were randomized to telmisartan 80 mg or placebo. After a mean treatment of 2 years, telmisartan showed a non significant lower rate of recurrent stroke versus placebo [880 versus 934; hazard ratio (HR) 0.95; 95% confidence interval (CI) 0.86-1.04]. However, in a post-hoc analysis, a significantly reduced number of strokes was observed in the telmisartan group compared to placebo (533 versus 608; HR 0.88; 95% CI 0.78-0.99; $p=0.042$) [83]. The ONgoing Telmisartan Alone and in combination with Ramipril Global Endpoint Trial (ONTARGET) and The Telmisartan Randomized AssessmeNt Study in aCE-iNtolerant subjects with cardiovascular Disease (TRANSCEND), compared telmisartan 80 mg versus ramipril 10 mg, and telmisartan 80 mg versus placebo (in patients intolerant to ACEIs), respectively. In the stroke subgroup, telmisartan 80 mg showed a trend toward reducing recurrent stroke versus ramipril 10 mg (HR 0.91; 95% CI 0.79-1.05). In a combined analysis of PROFESS and TRANSCEND, the incidence of the composite of stroke, myocardial infarction, or vascular death was 12.8% for telmisartan versus 13.8% for placebo (HR 0.91; 95% CI 0.85-0.98; $p=0.013$) [84].

The MOSES study showed for the first time superiority of an ARB (eprosartan) compared with a calcium channel antagonist (nitrendipine) in antihypertensive treatment for secondary stroke prevention [85]. In this study, 1,405 high-risk hypertensive stroke patients

were randomized. BP was reduced to a comparable extent without any significant differences between the 2 groups (from 150.7/84 mm Hg and 152.0/87.2 mm Hg with eprosartan and nitrendipine therapy to 137.5/80.8 mm Hg and 136.0/80.2 mm Hg, respectively). For the same level of BP control, eprosartan was significantly more effective than nitrendipine in reducing cerebrovascular morbidity and mortality (102 strokes in the eprosartan and 134 in the nitrendipine group; $p=0.03$).

Based on all these studies, the renin-angiotensin system (RAS) blockers (ACEIs and ARBs) are guideline-recognized, highly effective antihypertensive agents which offer benefits that extend beyond BP reduction alone. Experimental and clinical data suggest that reducing the activity of the RAS may have cerebroprotective effects. The Angiotensin II has hemodynamic properties (potent peripheral vasoconstrictor, stimulates aldosterone), action on endothelium (mediates endothelium dysfunction, vascular smooth cells hypertrophy), stimulates oxidative stress, including oxidation of low-density lipoprotein cholesterol (LDL-C), and inflammation (associated with expression of cellular adhesion molecules, chemotactic and proinflammatory cytokines) thus contributing to endothelial damage and arterial wall injury [86]. In a recent meta-analysis, after controlling for effects on BP control, ARBs appeared to be more effective than either ACEIs or β blockers in stroke prevention; however, CCBs were superior to RAS blockers in stroke prevention [87].

In conclusion, epidemiological studies and clinical trials confirmed the hypothesis of managing HTN to counteract the risk of stroke. The recommendation [74] to prevent recurrent stroke is to treat HTN aggressively (Class I, Level of Evidence A); although an absolute target of BP level has not been clearly defined, benefit has been associated with an average reduction of 10/5 mmHg, and normal BP levels have been defined as <120/80 mm Hg (Class IIa, Level of Evidence B). These recommendations extend to all patients with prior IS or TIA, irrespective of history or HTN, if BP reduction is considered appropriate (Class IIa, Level of Evidence B). Studies aimed at comparing different antihypertensive drugs are insufficient and have not reached clear results, but what is clear is that the effects of antihypertensive go beyond the simple control of BP. Diuretics alone or in combination with an ACEI are indicated (Class I, Level of Evidence A). The choice of a specific drug should be individualized based on drug and patient characteristics (extracranial occlusive disease, renal impairment, cardiac disease, and diabetes) (Class IIa, Level of Evidence B).

ATRIAL FIBRILLATION

Patients with non-valvular atrial fibrillation (AF) are at increased risk of stroke [13] [14]. The efficacy of warfarin over placebo has been consistently demonstrated across studies yielding an overall RRR of 68% (95% CI, 50% to 79%) and an absolute risk reduction (ARR) in annual stroke rate from 4.5% for controls to 1.4% in patients with adjusted-dose warfarin: 31 ischemic strokes will be prevented each year for 1000 patients treated [74]. Warfarin use has been also associated with a modest 1.3% annual rate of major bleeding as compared with 1% for patients on placebo or aspirin.

As compared to warfarin, a weaker efficacy of aspirin has been demonstrated in a pooled analysis of three clinical trials [88]. Analysis of an additional arm of the Atrial Fibrillation Clopidogrel Trial with Irbesartan for Prevention of Vascular Events (ACTIVE A) in patients

“unsuitable for vitamin K antagonists therapy” [89] showed superiority of combination therapy with aspirin and clopidogrel over aspirin alone in reducing the rate of stroke (2.4% vs 3.3% per year; $p > 0.001$). However, based on the observation that the rate of major vascular events combined with major hemorrhages did not significantly differed between the two groups, aspirin remains the treatment of choice in patients with AF and a clear contraindication to vitamin K antagonists. The European Atrial Fibrillation Trial (EAFT) [90] demonstrated superiority of anticoagulation over aspirin in preventing stroke recurrence in patients with history of IS or TIA: anticoagulation was significantly more effective than aspirin (HR 0.60; 95% CI 0.41-0.87). The incidence of major bleeding events was higher in the anticoagulation group, but low in both groups (2.8% and 0.9% per year); in absolute terms: 90 vascular events (mainly strokes) could be prevented if 1000 patients were treated with anticoagulation for one year. Aspirin demonstrated to be a valid, although less effective, alternative when anticoagulation was contraindicated, preventing 40 vascular events each year for every 1000 treated patients. More recently, systematic review of primary prevention studies in patients with non-valvular AF, demonstrated that adjusted-dose warfarin and related oral anticoagulants reduced stroke, disabling stroke and other major vascular events by about one third when compared with antiplatelet therapy [91]. For patients with AF who suffer an IS or TIA despite therapeutic anticoagulation, increasing the intensity of anticoagulation or adding an antiplatelet does not provide additional protection in preventing stroke while increases the risk of bleeding [88] [91].

Several new antithrombotic agents have been developed for stroke prevention in patients with non-valvular AF. New drugs for oral anticoagulation that do not exhibit the limitations of vitamin K antagonists include direct factor Xa inhibitors and direct thrombin inhibitors. In the Stroke Prevention Using Oral Thrombin Inhibitor in Atrial Fibrillation (SPORTIF) III (open-label, $n=3,407$) [92] and V (double-blind, $n=3,922$) [93], safety and efficacy of the oral direct thrombin inhibitor ximelagatran (fixed dose, 36 mg twice daily) were compared to warfarin (adjusted dose, target international normalized ratio [INR] 2.0-3.0) in patients with nonvalvular AF and at least 1 risk factor for stroke. Pooled analysis showed that the efficacy of ximelagatran was comparable (noninferior) with extremely well-controlled warfarin therapy in preventing stroke and systemic embolic events; the primary event rates were 1.65% per year and 1.62% per year in the warfarin and ximelagatran groups, respectively ($p=0.941$). In patients with a history of stroke or TIA (about 20% of the SPORTIF population), the event rates were 3.27% per year and 2.83% per year in the warfarin and ximelagatran groups, respectively ($p=0.625$). Intracranial hemorrhage occurred at a rate of 0.20% per year with warfarin and 0.11% per year with ximelagatran. Combined rates of minor and major bleeding were significantly lower with ximelagatran than with warfarin (32% per year vs 39% per year; $p < 0.0001$). The authors concluded that ximelagatran administered without coagulation monitoring or dose adjustment was as effective as well-controlled, adjusted-dose warfarin for prevention of stroke and systemic embolic events and was associated with significantly less total bleedings [93].

More recent trials have compared warfarin to dabigatran (RE-LY) [94], rivoraxaban (ROCKET-AF) [95], and apixaban (ARISTOTLE) [96], while in the AVERROES [97], safety and efficacy of apixaban (at a dose of 5 mg twice daily) was investigated as alternative treatment to aspirin (81 to 324 mg per day) in patients who were not suitable candidates for or were unwilling to receive vitamin K antagonist therapy. Taken together, these trials have demonstrated similar efficacy in patients with AF of these novel anticoagulants in both

primary and secondary stroke prevention, with significantly lower incidences of intracranial bleeding, compared with warfarin. Of note, the AVERROES was stopped prematurely because of a clear benefit in favor of apixaban was observed: apixaban reduced the risk of stroke or systemic embolism without significantly increasing the risk of major bleeding or intracranial hemorrhage. Based on the results of the RE-LY study [94], and with a modest absolute reduction of stroke or systemic embolism (1.7% versus 1.1%, $p < 0.001$), the most successful alternative anticoagulant is dabigatran, given at a dose of 150 mg twice daily.

A systematic review and meta-analysis of RCT has been recently performed to compare the efficacy and safety of new oral anticoagulants to those of warfarin in patients with AF [98]. The authors identified 3 studies, including 44,563 patients. Patients randomized to new oral anticoagulants had a decreased risk for all-cause stroke and systemic embolism (relative risk [RR] 0.78, 95% CI 0.67 to 0.92), ischemic and unidentified stroke (RR 0.87, 95% CI 0.77 to 0.99), hemorrhagic stroke (RR 0.45, 95% CI 0.31 to 0.68), all-cause mortality (RR 0.88, 95% CI 0.82 to 0.95), and vascular mortality (RR 0.87, 95% CI 0.77 to 0.98). Randomization to a new oral anticoagulant was associated with a lower risk for intracranial bleeding (RR 0.49, 95% CI 0.36 to 0.66).

Based on these findings, new oral anticoagulants seem to be superior to warfarin in preventing stroke and systemic embolism in patients with AF. Further, they appear to have a favorable safety profile, making them promising alternatives to warfarin. However, a recent meta-analysis of RCTs has assessed safety and efficacy outcomes in patients with AF treated with warfarin for stroke prevention compared with an alternative thromboprophylaxis strategy [99]. Eight high-quality RCTs published in the last 10 years were selected, with a total of 32,053 patients included. The pooled analysis yielded 55,789 patient-years of follow-up. Overall, the time spent in the therapeutic range was 55% to 68%. The annual incidence of stroke or systemic embolism in patients with AF taking warfarin was estimated to be 1.66% (95% CI, 1.41%-1.91%).

Major bleeding rates varied from 1.40% to 3.40% per year across the studies. The risk of stroke per year was significantly higher in elderly patients (2.27%), female patients (2.12%), patients with a history of stroke (2.64%), and patients reporting no previous exposure to vitamin K antagonists (1.96%). The authors concluded that warfarin used as a stroke prevention agent in patients with AF was associated with a significantly lower rate of recurrent stroke or systemic embolism estimated compared to other antithrombotic treatments.

Conclusions: patients with IS or TIA with non-valvular AF should receive anticoagulation with a vitamin K antagonist (target INR 2.5, range 2-3) (Class I, Level of Evidence A); for patients unable to take oral anticoagulants, aspirin alone is recommended (Class I, Level of Evidence A); combination therapy with aspirin plus clopidogrel has the same contraindication of warfarin due to similar rate of bleeding complications (Class III, Level of Evidence B) [74].

TREATING HYPERLIPIDEMIA

Cholesterol levels represent an important and modifiable risk factor for coronary artery disease (CAD). However, the epidemiological association between cholesterol and stroke is

controversial: direct and moderately strong, direct but fairly weak, J shaped unclear and absent. Observational studies may be limited because cholesterol may have different effects on different stroke types; further, the incidence of stroke is lower and occurs later as compared to CAD. An association between serum cholesterol levels and both incident and recurrent stroke rate has not been clearly demonstrated. The Prospective Studies Collaboration [100] evaluated this association in pooled data of 45 prospective observational cohorts, with a total of 450,000 individuals, a mean follow-up of 16 years and a total of 13,397 strokes recorded. The analysis detected a 'flat effect' of increasing cholesterol levels on stroke risk. Despite only weak or no association of cholesterol levels with stroke, treatment with statins has consistently shown positive effects. The Scandinavian Simvastatin Survival Study (4S) [101] was a placebo-controlled trial which detected a 30% RRR in incidence of any stroke in patients treated with simvastatin as compared to placebo. In the Heart Protection Study (HPS) [102] 20,536 high-risk patients (CAD, occlusive arterial disease, diabetes mellitus) were enrolled in 69 UK hospitals: 13,379 (65%) with CAD, 3,280 (16%) with stroke+CAD, and 1,822 (9%) with stroke only. Patients were randomized to receive 40 mg simvastatin or placebo, and they had a follow-up of 5.5 years. Statin treatment was associated with a 27% RRR for all strokes, and a 25% RRR for ischemic stroke. However, no clear RRR in stroke recurrence was observed in patients with a prior stroke and no known CAD. A meta-analysis that included 16 statin trials with 34,000 patients and 860 strokes evidenced an overall 25% RRR for stroke (14% to 35%), with a non-significant 15% RRR (-28% to 43%) for primary, and a significant 35% RRR (18% to 49%) for secondary stroke prevention [103]. The Stroke Prevention by Aggressive Reduction in Cholesterol Levels (SPARCL) [104] evaluated secondary stroke prevention. The study demonstrated a 16% risk reduction of recurrent fatal or non fatal stroke in patients randomized to 80 mg atorvastatin versus placebo.

In secondary prevention of stroke, the use of statins has shown a positive effect in both decreasing progression and/or inducing regression of carotid artery plaque and stroke recurrence. By analyzing data from all available studies on statin treatment and stroke risk, Amarencu et al. [105] demonstrated a linear relationship between low-density lipoprotein-cholesterol (LDL-C) values and RRR of stroke. Each 10% reduction in LDL-C was estimated to reduce the risk of all strokes by 15.6% (95% CI, 6.7 to 23.6). This analysis also demonstrated a strong correlation between progression of carotid intima-media thickness (IMT) and LDL-C reduction.

The question is: why should statins prevent ischemic stroke? The possible explanations are two: lipid effects (LDL-C lowering), and ii) non-lipid effects. Among these the following have been demonstrated: i) stabilization of atherosclerotic plaque; ii) improvement of the endothelial function; iii) decrease in the inflammation; iv) decrease of platelet aggregation; v) a direct lowering effect of blood pressure and vi) a decrease in cardiac emboli, and vii) miscellaneous (reduced left ventricular hypertrophy, HTN, effects on endothelial progenitor cells). Experimental data suggests that LDL-C may damage the vascular endothelium by oxidation of lipids, glycation and oxidation of proteins. Its accumulation under the endothelium leads to activation of inflammation which triggers movements of macrophages and T cells into the intima, plaque development and progression, as well as development of a fibrous cap over the lipid core, which ultimately leads to plaque rupture and thrombus formation. Direct evidence of the molecular mechanisms modulating the plaque composition and its instability, and of a direct effect of statins on the inflammatory processes that are supposed to be involved in the plaque rupture have been demonstrated [106].

The association of total and high-density lipoprotein cholesterol (HDL-C) with stroke risk is unclear. This association has been recently investigated in among 58,000 Finnish people aged 25 to 74 years. During a mean follow-up period of 20.1 years, 3,914 participants developed incident stroke (3,085 were ischemic). Low levels of HDL-C and high total/HDL cholesterol ratio were associated with increased risks of ischemic stroke in both sexes. These associations attenuated after adjustment for body mass index, blood pressure, and history of diabetes [107]. Two recent meta-analyses have shown that ezetimibe co-administration with a statin provides significant additional lipid-lowering effect, allowing more patients to achieve low density lipoprotein cholesterol (LDL-C) target values [108] [109]. Although reduction of LDL-C remains the primary goal for lipid-lowering interventions, other targets (e.g., HDL-C and triglycerides) may also be important. However, there is no definitive evidence showing that raising HDL-C levels in patients on statins will result in a significant reduction in vascular events [110] [111]. Similarly, it is not clear if triglycerides levels are independent predictors of vascular risk [112].

Conclusions: statins are recommended to prevent the first stroke in high-risk patients to lower LDL-C level <100 mg/dL; an LDL-C <70 mg/dL is recommended for highest risk (high risk: any of LDL >4.1, age >45M/55F, positive family history, smoking, HTN, left ventricular hypertrophy; highest risk: DM or established atherosclerosis) (Class I, Level of Evidence A). New recommendation for secondary stroke prevention: on the basis of the SPARCL trial [74], statin treatment with intensive lipid-lowering effects is recommended to reduce the risk of stroke and cardiovascular events for patients with IS or TIA, evidence of atherosclerosis, an LDL-C level $\geq$ 100 mg/dL, and without known coronary artery disease (Class I, Level of Evidence B). In these patients, a target reduction of at least 50% in LDL-C or a target LDL-C level <70 mg/dL is recommended (Class IIa, Level of Evidence B). Patients with IS or TIA with low HDL-C may be considered for treatment with niacin or gemfibrozil (Class IIb, level B).

DIABETES

Epidemiological studies show that diabetes is a risk factor for first ischemic stroke, while data on stroke recurrence are more sparse [12] [74]. Further, the role of tight glycemic control in reducing the risk of stroke is still uncertain [113]. Patients with diabetes have higher mortality, more severe disability, and slower recovery after a stroke, as well as higher rates of stroke recurrence at 1 month (4.9% vs 2.6%) and at 2.6 years (15.2% vs 11.4%) compared to non-diabetic stroke patients [114] [115]. In addition, the ten-year risk of ipsilateral ischemic stroke after carotid endarterectomy is higher in the presence of diabetes (HR 2.24; 95% CI 1.35-3.74; $p=0.002$) [116]. The United Kingdom Prospective Diabetes Study (UKPDS) was a landmark study in the treatment of type 2 diabetes from the time of diagnosis [117]. This study has demonstrated that intensive treatment of type-2 diabetes versus standard treatment determined a 12% RRR the event rate (including stroke).

The Heart Outcomes Prevention Evaluation (HOPE) [118] enrolled 3,577 people with diabetes, who had a previous cardiovascular event or at least one other cardiovascular risk factor, were randomly assigned to ramipril (10 mg/day) or placebo. The combined primary outcome was myocardial infarction, stroke, or cardiovascular death. The study was stopped 6

months early (after 4.5 years) because of a consistent benefit of ramipril compared with placebo: ramipril lowered the risk of the combined primary outcome by 25% (95% CI 12-36, $p=0.0004$), stroke by 33% (10-50), and, among other outcomes, total mortality by 24% (8-37). After adjustment for the changes in SBP and DBP, ramipril still lowered the risk of the combined primary outcome by 25% (12-36, $p=0.0004$). The study demonstrated that the vasculoprotective effect of ramipril in diabetic patients was greater than that attributable to the decrease in blood pressure.

A secondary analysis of the Stroke Prevention by Aggressive Reduction in Cholesterol Levels (SPARCL) trial, which tested the effect of treatment with atorvastatin in reducing stroke in subjects with a recent stroke or TIA, investigated the effects of treatment in subjects with type 2 DM or metabolic syndrome (MetS) [119]. In this subanalysis, subjects with type 2 DM ($n=794$) had increased risks of stroke (HR 1.62; 95% CI, 1.33-1.98; $p<0.001$), and major cardiovascular events (HR 1.66; 95% CI, 1.39-1.97; $P<0.001$) compared with patients with neither diabetes nor MetS ($n=3,295$). This exploratory analysis found no difference in the effect of statins in reducing these events in subjects with or without type 2 DM.

Intensive glucose therapy did not prove effective treatment in reducing the rate of cardiovascular events or death in patients with type 2 DM and prior history of cardiovascular disease, stroke, or vascular risk factors. In the Action to Control Cardiovascular Risk in Diabetes (ACCORD) trial [12] [120], 10,251 diabetic patients were randomly assigned to intensive glucose control ($HbA_{1c}<6\%$) versus standard treatment ($HbA_{1c} 7-7.9\%$). The study was interrupted after 3.5 years of follow-up because of higher mortality in the intensive treatment group. No difference in rate of non-fatal stroke was observed between the two groups (HR 1.06; 95% CI 0.75-1.50; $p=0.72$). In the Action in Diabetes and Vascular Disease (ADVANCE) trial [121] 11,140 diabetic patients were randomized to intensive treatment ($HbA_{1c}\leq 6.5\%$) versus standard treatment ($HbA_{1c}\leq 7\%$). The two groups did not differ in occurrence of non-fatal stroke (HR 0.94; 95% CI 0.84-1.06; $p=0.32$). Also in the Veterans Affairs Diabetes Trial (VADT) trial [122] intensive glucose control did not reduce combined vascular outcomes compared to standard care (HR 1.07; 95% CI 0.81-1.42; $p=0.62$).

The PROspective pioglitAzone Clinical Trial in macroVascular Events (PROactive) was designed to evaluate efficacy of pioglitazone efficacy in preventing vascular events in patients with type 2 DM. In the subset of patients with history of stroke enrolled in the study ($n=486$ in the pioglitazone group and $n=498$ in the placebo group), pioglitazone was associated with a 47% RRR in recurrent fatal and non-fatal stroke (HR, 0.53; 95% CI, 0.34 to 0.85; $p=0.008$), and 25% RRR in stroke, MI, or vascular death (HR, 0.72; 95% CI, 0.53 to 1.00; $p=0.046$) [123].

Intensive hypertensive treatment (SBP <120 mmHg) in type 2 DM has not been supported by a recent analysis of the ACCORD patients. In this study the annual rate of the primary outcome (i.e., composite outcome was nonfatal myocardial infarction, nonfatal stroke, or death from cardiovascular causes) was 1.87% in the intensive BP treatment and 2.09% in the standard-therapy group (HR, 0.88; 95% CI 0.73 to 1.06; $p=0.20$). The annual rates of stroke were 0.32% and 0.53%, respectively (HR, 0.59; 95% CI, 0.39 to 0.89; $P=0.01$). Serious adverse events attributed to antihypertensive treatment were significantly more frequent in the intensive-therapy group (3.3% versus 1.3%; $p<0.001$) [120].

Conclusions: in patients type 2 DM with history of TIA and stroke, glucose control is recommended (Class I, Level of Evidence B) [124] [125]. Levels of $HbA_{1c} <6.5\%$ should not be achieved in diabetic patients with history of cardiovascular disease or vascular risk factors

[120] [121] [122]. Based on the current knowledge, a target BP <130/80 mmHg for patients with type 2 DM is recommended [124] [125]. An ongoing trial will provide further insight on pioglitazone usefulness in preventing recurrent stroke in diabetic patients.

ANTIPLATELET THERAPY

Within the established efficacy in stroke prevention through pharmacological and lifestyle control of modifiable vascular risk factors, a central role is played by antiplatelets. Aspirin represents the prototype of all antiplatelets. It acts by inhibiting the cyclo-oxygenase pathway with subsequent reduction in platelet thromboxane A₂ synthesis and partial block of the final step of platelet aggregation. In a recent meta-analysis of 16 secondary prevention trials (17,000 individuals at high average risk, 43,000 person-years, 3,306 serious vascular events) comparing long-term aspirin versus control, treatment with aspirin reduced of about a fifth the rate of total stroke (2.08% versus 2.54% per year, $p=0.002$), with a non-significant increase in haemorrhagic stroke [126]. Second generation platelet inhibitors such as thienopyridines (e.g., ticlopidine or clopidogrel) work by blocking the platelet adenosine diphosphate (ADP) receptor; they may offer greater preventive efficacy, especially in specific populations of atherothrombotic disease patients. In the Clopidogrel versus Aspirin in Patients at Risk of Ischemic Events (CAPRIE) study [127], over 19,000 patients at high risk of recurrent stroke were randomized to either treatment with clopidogrel 75 mg/day or aspirin 325 mg/day for a mean follow-up period of 1.9 years. Clopidogrel reduced the risk of major cardiovascular events (IS, MI, or vascular death) in a small but statistically significant manner compared with aspirin (RRR 8.7%; 95% CI, 0.3 to 16.5; $p=0.043$). However, sub-group analysis revealed that the RRR was statistically significant only in PAD but not in stroke nor in myocardial infarction (MI) patients.

In the Management of Atherothrombosis with Clopidogrel in High-risk patients with recent transient ischaemic attack or ischaemic stroke (MATCH) study [128] 7,599 patients were randomized to receive either clopidogrel 75 mg plus aspirin 75 mg or clopidogrel 75 mg alone. Combination therapy was not superior to clopidogrel alone in preventing primary composite outcomes (IS, MI, vascular death or rehospitalisation for any ischemic event), with significant increase in major bleeding complications. The Clopidogrel for High Atherothrombotic Risk and Ischemic Stabilization, Management, and Avoidance (CHARISMA) trial [129] evaluated whether the addition of clopidogrel to aspirin better prevented recurrent stroke. In this trial 15,603 patients with cardiovascular disease or multiple vascular risk factors for cardiovascular disease (35% had history of cerebrovascular diseases in the previous 5 years) were randomized to clopidogrel 75 mg plus low-dose aspirin (75-162 mg) or placebo plus aspirin (75-162 mg). The two groups did not differ in the rates of non-fatal IS (1.7% versus 2.1%; $p=0.07$) and had similar rates of intracerebral hemorrhage (0.3%). Patients in the combination arm treatment had a higher rate of moderate bleeding (not of severe or fatal). The study did not demonstrate superiority of combination treatment over aspirin in the subgroup of patients with prior history of IS or TIA.

Dipyridamole is a phosphodiesterase inhibitor which inhibits platelet aggregation. The European/Australasian Stroke Prevention in Reversible Ischemia Trial (ESPRIT) [130] was a randomized, non blinded study, comparing aspirin (30-325 mg) and dipyridamole (200 mg

twice daily; 83% extended-release dipyridamole) versus aspirin (30-325 mg) alone in 2,763 patients who had TIA, monocular blindness, and minor stroke (modified Rankin score ≤ 3) in the 6 months prior to enrollment. The mean follow-up was 3.5 years. Combined treatment conferred an absolute risk reduction of 1% for primary outcome (death from all vascular causes, nonfatal stroke, nonfatal myocardial infarction, or fatal bleeding complications). Despite few study weaknesses have been detected (non-blinded, nonstandard aspirin doses, divergence of significance between the on-treatment and intention-to-treat analyses, high rate of discontinuation therapy in the combination treatment arm), this study provided additional evidence of superiority of combined therapy with aspirin plus extended-release dipyridamole compared to aspirin alone in stroke prevention in patients with non-cardioembolic IS. Further, similar rates of recurrent stroke were observed with combination dipyridamole plus aspirin compared with clopidogrel, with no evidence that either of the two treatments was superior to the other in the prevention of recurrent stroke [131].

In the PERFORM study [132], the selective thromboxane-prostaglandin receptor antagonist terutroban (30 mg per day) was compared with aspirin (100 mg per day) in prevention of IS and cardiovascular events in patients with a recent non-cardioembolic IS. The primary efficacy endpoint was a composite of any IS, any MI, or other vascular death. The study was stopped prematurely for futility, because it showed similar rates of the primary endpoint with terutroban and aspirin, without safety advantages for terutroban.

Recommendations for patients with history of non cardioembolic stroke or TIA are: aspirin (50-325 mg/die) monotherapy (Class I, Level of Evidence A), the combination of aspirin 25 mg and extended-release dipyridamole 200 mg twice daily (Class I, Level of Evidence B), and clopidogrel 75 mg monotherapy (Class IIa, Level of Evidence B), are all acceptable options as initial therapy for prevention of recurrent stroke or other cardiovascular events. Clopidogrel is reasonable alternative option in patients allergic to aspirin (Class IIa, Level of Evidence C). The addition of aspirin to clopidogrel increases the risk of hemorrhage, and combination therapy is no recommended unless specific indications exist (i.e., coronary and other vascular stent or acute coronary syndrome) (Class III, Level of Evidence A). For patients who have an IS while on aspirin, alternative antiplatelets may be considered although this has not been assessed yet by RCTs (Class IIb, level of Evidence C) [74].

CILOSTAZOL IN THE MANAGEMENT OF ATHEROSCLEROSIS

Cilostazol is a selective and potent selective type III phosphodiesterase (PDE 3A) inhibitor that blocks cyclic adenosine monophosphate (cAMP) phosphodiesterase (PDE) in platelets and smooth muscle cells (SMCs), leading to inhibition of platelet aggregation and vasodilation, with potential use in atherosclerotic conditions, including stroke [133] [134]. Other properties of cilostazol are the inhibition of the uptake of adenosine, a platelet inhibitory agent, the suppression of platelet membrane glycoprotein P-selectin, which is involved in the interaction among platelets, leukocytes and vascular endothelial cells, responsible for the inflammatory and prothrombotic states induced by cerebral ischemia/reperfusion [134]. Cilostazol also has antiatherogenic properties: activates endothelial nitric oxide synthase (NOS) through its phosphorylation resulting in increased

nitric oxide (NO) release and angiogenic effect [135]; inhibits the expression of endothelial-neutrophil adhesion molecules mediated by high-glucose concentration, with potential application against vascular injury mediated by hyperglycemia [136]; increases lipoprotein lipase activity which is responsible for triglycerides hydrolyzation, reducing serum triglycerides and increasing HDL-C levels; inhibits the macrophage uptake of oxidized LDL by scavenger receptors (a major cellular event contributing to foam cell and fatty streak formation) [137].

Cilostazol efficacy has been tested in patients with periphery artery disease (PAD) with positive results in improving claudication [138]. A recent study evaluating the bleeding effects of platelet inhibitors (aspirin 325 mg/day, clopidogrel 75 mg/day and cilostazol 100 mg bid) each alone or in combination [139] [140], evidenced that the mean baseline bleeding time significantly increased after aspirin only, clopidogrel only, combination of aspirin and clopidogrel, and combination of all three agents; but not after cilostazol alone. The addition of cilostazol to aspirin or clopidogrel did not determine further significant increase in bleeding time compared to aspirin alone or clopidogrel alone.

The Cilostazol Stroke Prevention Study (CSPS) [141] [142] was designed to evaluate safety and effectiveness of cilostazol in prevention recurrent stroke. In this double-blind, placebo-controlled trial, 1,095 patients (544 receiving cilostazol 100 mg twice daily and 548 receiving placebo) were enrolled. The recurrence rate of IS was significantly reduced by cilostazol with a 41.7% RRR (number needed to treat=41). A subgroup analysis showed that patients with lacunar infarcts had a significant reduction in recurrence of IS whereas no statistical significance was reached in patients with atherothrombotic or mixed-type infarctions. The most commonly observed adverse event in the cilostazol treated group was headache (12.8%), palpitations (5.3%) and increase in pulse rate (19%). Headache and palpitations resulted in treatment discontinuation in some cases. This is in line with another PDE inhibitor, dipyridamole, currently used in stroke prevention, which caused withdrawal of therapy in 26% of patients in the ESPRIT trial [130].

Further potential use of cilostazol in clinical practice may derive from the benefits observed in diabetic patients. In patients with type 2 DM cilostazol 100-200 mg/day significantly prevented IMT progression, reduced the number of silent brain infarctions which have been associated with increased risk of developing dementia [143] [144]. Based on the results and the observed reduced efficacy of antiplatelets in diabetic patients [145], cilostazol might represent an alternative to standard care at least in the subgroup of patients with lacunar stroke. This hypothesis was tested in the Cilostazol versus Aspirin for Secondary Ischemic Stroke Prevention (CASISP) trial [146], which was a pilot, multicentre, double-blind trial, which randomly assigned 301 patients to cilostazol and 299 patients to aspirin treatment, with a follow-up period of 12 to 18 months. The primary endpoint was any recurrence of stroke (IS, haemorrhagic stroke, or subarachnoid hemorrhage) during the trial period, as assessed by follow-up MRI study. Cilostazol was associated with not-significant RRR of stroke (HR 0.62; 95% CI 0.30-1.26; $p=0.185$), and significantly lower rates of symptomatic and asymptomatic cerebral hemorrhages (7 vs 1, $p=0.034$). The results suggested that cilostazol appeared to be a more effective and safer alternative to aspirin in secondary stroke prevention, and that further trials were needed. Of interest, it should be further investigated whether a reduced risk of intracranial bleeding complications is peculiar of PDE inhibitors, as suggested by the reduced occurrence of cerebral hemorrhage observed in patients treated with dipyridamole plus aspirin as compared to aspirin alone in the ESPRIT [130]. In addition, a post-hoc analysis in patients

with cerebrovascular events enrolled in the CASTLE trial [147] detected a 3% absolute RR of cerebrovascular events compared to placebo (3.2% versus 6.1%; $p < 0.05$). This represents an important finding considering the 2-fold increased risk of cerebrovascular events in patients with PAD compared to patients without. Further, a RCT of 135 patients has shown that treatment with cilostazol significantly reduced progression of symptomatic intracranial arterial stenosis compared to placebo [148].

More recently, a systematic review assessed safety and effectiveness of cilostazol compared with aspirin in the prevention of stroke and other serious vascular events in patients with previous IS or TIA of arterial origin [149]. Two RCTs with 3,477 Asian participants were selected. Compared with aspirin, cilostazol was associated with a significantly lower risk of composite outcome of vascular events (6.77% versus 9.39%; RR 0.72, 95% CI, 0.57 to 0.91), haemorrhagic stroke (0.53% versus 2.01%, RR 0.26, 95% CI, 0.13 to 0.55), and minor adverse effects (8.22% versus 4.95%, RR 1.66, 95% CI 1.51 to 1.83).

Based on the available data, cilostazol seems to be more effective than aspirin in the prevention of vascular events in high-risk Asian patients. Further RCTs testing larger cohorts of vascular patients are needed in order to address the exact potential of cilostazol in the management of atherosclerosis and stroke prevention.

STROKE REHABILITATION

Stroke is one the leading causes of long-term disability in the developed countries. Its social impact is not only determined by the huge number of individuals that live with the effects of stroke, but there are also millions of relatives who care for stroke survivors and whose own lives are personally affected. According to the National Stroke Association 10% of stroke survivors recover almost completely, 25% recover with minor impairments, 40% experience moderate to severe impairments that require special care, 10% require care in a nursing home or other long-term facility, 15% die shortly after the stroke. Moreover, approximately 14% of stroke survivors experience a second stroke in the first year following a stroke [150].

A successful rehabilitation depends on several heterogeneous factors such as the amount of damage to the brain, the level of the rehabilitation team, the cooperation of family and friends, and the timing of rehabilitation. In fact, a crucial issue is that the earlier the rehabilitative programs begin, the more likely stroke patients can expect a more relevant clinical improvement. The goal of rehabilitation is to enable an individual who has experienced a stroke to reach the highest possible level of independence and be as productive as possible. Because stroke survivors often have complex rehabilitation needs, progress and recovery are unique for each person. Although a majority of functional abilities may be restored soon after a stroke, recovery is an ongoing process. The available scientific literature suggests that poststroke rehabilitation intervention is significantly more effective when it is delivered in the early phase of recovery (<6 months). Evidence supports that better functional outcome is determined by rehabilitation that is initiated promptly [151]. and based on intensive, especially multisensory, stimulation [152, 153]. This kind of stimulation is associated with increased adaptive plasticity of the brain in the early poststroke stages [154-157]. Indeed, optimal timing and dosing of rehabilitation interventions are yet unresolved

issues. For instance, high-intensity constraint-induced therapy (CIT), known to enhance activity in the lesioned hemisphere [158, 159], led to less improvement in upper extremity function compared to traditional therapy or low-intensity constraint-induced therapy, when administered early after stroke in the VECTORS study [160]. In this case, it has been proposed that an excessive disinhibition of the lesioned hemisphere that is induced very early after stroke may be harmful [161, 162].

Rehabilitative therapy should begin in the acute-care hospital after clinical stabilization, usually within 24 to 48 hours after the stroke. The first steps involve promoting independent movement because many individuals are paralyzed or seriously weakened. Depending on many factors—including the extent of the initial injury—patients may progress from sitting up and being moved between the bed and a chair to standing, bearing their own weight, and walking, with or without assistance. The neurological disabilities that are caused by an acute stroke mainly depend upon which area of the brain is damaged and how large is the lesion. However, as all stroke clinicians know, these symptoms may be extremely heterogeneous even if the lesions look quite similar. Generally, stroke can cause the following main types of disabilities: motor impairment; sensory disturbances including pain; aphasia; problems with thinking and memory; and emotional disturbances.

In a classic report, Twitchell described in detail the pattern of motor recovery following stroke. [150] At onset, the upper extremity (UE) is more involved than the lower extremity (LE), and eventual motor recovery in the UE is less than in the LE. The severity of UE weakness at onset and the timing of the return of movement in the hand are important predictors of eventual motor recovery in the UE. A systematic review of 58 studies confirms the most important predictive factor for upper limb recovery following stroke is the initial severity of motor impairment or function [163]. The prognosis for return of useful hand function is unfavorable when UE paralysis is complete at onset or grasp strength is not measurable by 4 weeks. However, about 9% of patients with severe UE weakness at onset may gain good recovery of hand function, and about 70% of patients showing some motor recovery in the hand by 4 weeks make a full or good recovery. Full recovery, when it occurs, usually is complete within 3 months of onset. Bard and Hirshberg asserted that if no initial motion is noticed during the first 3 weeks or if motion in one segment is not followed within a week by the appearance of motion in a second segment, the prognosis for recovery of full motion is not favorable. Although most recovery from stroke takes place in the first 3 months, and only minor additional measurable improvement occurs after the 6 months following onset, recovery may continue over a longer period of time in some patients who have significant partial return of voluntary movement [164, 165].

At least one-fourth of all stroke survivors experience language impairments, involving the ability to speak, write, and understand spoken and written language. A stroke-induced injury to any of the brain's language-control centers can severely impair verbal communication. Moreover, stroke can cause damage to parts of the brain responsible for memory, learning, and awareness. Stroke survivors may have dramatically shortened attention spans or may experience deficits in short-term memory. Individuals also may lose their ability to make plans, comprehend meaning, learn new tasks, or engage in other complex mental activities. Two fairly common deficits resulting from stroke are anosognosia, an inability to acknowledge the reality of the physical impairments resulting from stroke, and neglect, the loss of the ability to respond to objects or sensory stimuli located on the stroke-impaired side. Some emotional disturbances and personality changes are caused by the

physical effects of brain damage. Clinical depression appears to be the emotional disorder most commonly experienced by stroke survivors. Signs of clinical depression include sleep disturbances, a radical change in eating patterns that may lead to sudden weight loss or gain, lethargy, social withdrawal, irritability, fatigue, self-loathing, and suicidal thoughts. Post-stroke depression can be treated with antidepressant medications and psychological counseling.

All these complex syndromes can be accompanied by motor disorders and make the pathway toward a motor functional recovery more difficult and long.

NEUROPLASTICITY AND MECHANISMS OF RECOVERY

Brain plasticity is the ability of the nervous system to modify its structural and functional organization [166]. The most plausible forms of plasticity are collateral sprouting of new synaptic connections and unmasking of previously latent functional pathways. Other mechanisms of plasticity include assumption of function by undamaged, redundant neural pathways, reversibility from diaschisis, denervation supersensitivity, and regenerative proximal sprouting of transected neuronal axons. Experimental evidence indicates that plasticity can be altered by several external factors, including pharmacologic agents, electrical stimulation, and environmental stimulation. A key aspect of neuroplasticity that has important implications for rehabilitation is the fact that the modifications in neuronal networks are use-dependent. Animal experimental studies and clinical trials in humans have shown that forced use and functional training contribute to improved function. On the other hand, techniques that promote nonuse may inhibit recovery. In the past, the conventional wisdom was that benefits from rehabilitation were achieved primarily through training patients in new techniques that compensate for impairments (for example, using the uninvolved hand to achieve self-care independence). This approach avoided intense therapy on the weak upper limb. Currently, it is recognized that repeated participation by patients in active physical therapeutic programs probably provides direct influence on the process of functional reorganization in the brain and enhances neurologic recovery.

The discovery of the synaptic phenomenon of Long Term Potentiation (LTP) and Long Term Depression (LTD) demonstrated how the brain could adapt to encode novel experience at the level of the synapse or 'neuroplasticity' [166]. The most widely recognized forms of plasticity are learning, memory, and recovery from brain damage. At the synaptic level, plasticity induces dendritic spine formation, pruning, and remodeling, calcium channel regulation and changes in glutamatergic receptors. More recently, LTP and LTD of inhibitory GABAergic synapses have been described, and as is the case for glutamatergic synapses, both ionotropic and metabotropic mechanisms are involved. Many other neurotransmitters contribute to plasticity or its regulation, for example dopamine. While these mechanisms have been extensively investigated and clarified in animal models, only in recent years there have been attempts aimed to study how the human brain undergoes these crucial plastic changes [167]. A major step forward has been provided by using novel *in vivo* neurostimulation and neuroimaging techniques that have now allowed studying the same process in humans non-invasively. In particular, neurostimulation techniques like repetitive transcranial magnetic stimulation (rTMS) and transcranial direct current stimulation (TDCS) have been developed

to induce long-lasting changes in specific areas of the cerebral cortex that can be assessed with a high intra-individual reliability across different sessions, usually by means of motor evoked potentials (MEPs). rTMS protocols using patterned stimulation such as theta burst stimulation (TBS) have been more recently developed [168] using principles from tissue models and Hebbian models of plasticity, so that much lower intensities or shorter periods of stimulation are necessary to produce bidirectional LTP- and LTD-like changes in cortical excitability determined by changes of the MEP amplitude. Similar long lasting bidirectional changes can be obtained using tDCS [169]. Its primary mechanism of action involves changes in neuronal hyperpolarization, accomplished by cathodal tDCS and subthreshold neuronal depolarization, induced by anodal tDCS. The TBS and TDCS after-effects are NMDA receptor dependent [170] and affected by neuromodulators, such as dopamine, acetylcholine, and adrenaline [171]. Thus, the physiologic effects of TBS and tDCS show similarities to LTP and LTD, as induced in animals and in vitro brain slices. Crucially, these non-invasive brain stimulation (NIBS) techniques not only allow to investigate the mechanisms of cortical plasticity in healthy humans as well as in neuropsychiatric disorders, but the induction of neuroplasticity by means of NIBS is considered a promising tool in treating several neurological conditions [172, 173]. However, to be effective, these interventions must take into account the range of neurological disorders, their heterogeneity even within well-defined and characterized conditions, and the diverse time courses over which they act. Thus plasticity can be regarded as functional or dysfunctional, and this distinction is likely to be important for the application of NIBS in clinical situations. After brain lesions like stroke, cortical areas that are remote from the structural damage, such as the primary motor cortex, can reorganize to facilitate motor performance as well as motor learning [172, 173]. The available evidence suggests that cortical reorganization accompanies recovery of motor function after stroke. One form of cortical reorganization involves the modulation of interactions between the primary motor cortices in the ipsilesional hemisphere (same as the stroke), and the contralesional hemisphere [174, 175]. The influence of abnormal interhemispheric interactions on normal and abnormal cognitive functions after brain lesions has been reported in the fields of language and spatial orientation [176].

According to the model of interhemispheric competition, excessive inhibition of the lesioned hemisphere by the contralesional hemisphere may contribute to hand motor impairment in patients with mild motor deficits [174, 175]. Within this framework, rTMS has emerged as a potential tool to restore interhemispheric balance and improve hand motor performance. While high-frequency rTMS (HF-rTMS) often increases M1 excitability, low-frequency rTMS (LF-rTMS) has the opposite effect [173]. Up-regulation of excitability in the lesioned hemisphere by HF-rTMS or down-regulation of the contralesional hemisphere by LF-rTMS can facilitate movement of the paretic hand [173]. Both strategies, as well as their combination, have yielded encouraging results when applied to patients with mild hand motor impairment in the subacute and chronic stages after stroke [172].

Apart from NIBS methods, other strategies can be potentially useful to drive neuroplasticity and enhance mechanisms of recovery. Results from a systematic review indicate that modified constraint-induced movement therapy (CIMT) is more effective than traditional rehabilitation in reducing a patient's disability level [177]. It can improve upper extremity ability and increase movement spontaneity. Further studies are needed on CIMT's effectiveness in kinematic analysis. In a pilot, randomized, clinical trial, with a 6-month follow-up, the practicality and efficacy of conventional neurological therapy, constraint-

induced therapy, and therapeutic climbing to improve minimal-to-moderate arm and hand function in stroke patients was evaluated. The study concluded that improvement of arm and hand function in the intermediate term was best achieved using the constraint-induced therapy approach [178].

The use of robotic systems to complement standard poststroke multidisciplinary programs is a recent approach that looks very promising; robotic devices can provide high-intensity, repetitive, task-specific, interactive treatment of the impaired limb (passive and/or active-assisted exercises) and can objectively and reliably monitor patients' motor progress, measuring changes in movement kinematics and forces [179, 180]. It is appropriate to consider the robot as an advanced tool to be used under the therapist's direction—a tool that can implement relatively simple repetitive and labor-intensive therapies. Clinical decisions should be managed by the rehabilitation team and, when appropriate, planned and executed on the robot; this approach should be part of an integrated set of tools that also includes simpler nonrobotic approaches [181].

In a recent Cochrane review, Mehrholz et al. showed that the use of electromechanical devices in rehabilitation may not significantly improve activities of daily living (ADLs), although they did find evidence that upper-arm motor function and strength may improve [182]. Moreover, a recent multicenter, randomized, controlled trial involving 127 patients with moderate-to-severe upper-limb impairment 6 months or more after a stroke, was performed in order to verify the potential of Robot-assisted therapy for long-term upper-limb impairment after stroke. In patients with long-term upper-limb deficits after stroke, robot-assisted therapy did not significantly improve motor function at 12 weeks, as compared with usual care or intensive therapy, although in secondary analyses, robot-assisted therapy improved outcomes over 36 weeks as compared with usual care but not with intensive therapy [183]. Thus, the actual role of robot-assisted therapy in poststroke rehabilitation remains to be clarified, and to date, no guidelines exist on how the design and use of such devices might increase their efficacy [182].

Chapter 3

ISCHEMIC STROKE PREVENTION IN VIETNAM

ABSTRACT

Ischemic stroke has a high burden not only in developed countries but also in developing countries. In Vietnam, rapid economic development and modernization during the past two decades has led to dramatic increases in many chronic diseases, including ischemic stroke. A previous study of stroke conducted in the southern region of Vietnam reported an age-adjusted prevalence of 608 per 100,000 people, while mortality and incidence of the disease were estimated to be about 131 and 250 per 100,000 people, respectively. Hypertension was identified as one of the most important risk factors. However, recent epidemiologic information about ischemic stroke for the Vietnamese population is lacking. Unlike non-modifiable factors (e.g., age, gender, race and genetic predisposition), modifiable and potentially modifiable lifestyle-related factors such as tobacco smoking, alcohol consumption, poor diet, physical inactivity, overweight and obesity, have been recognised as vital for both primary and secondary prevention in the literature. The purpose of this chapter is to review the epidemiology and risk factors of ischemic stroke, with implications on the prevention of this emerging chronic disease in Vietnam.

INTRODUCTION

Strokes are caused by disruption of the blood supply to the brain. This may result from either blockage (ischemic stroke) or rupture of a blood vessel (haemorrhagic stroke) [1]. Each year about 795 000 people experience a new or recurrent stroke. About 610 000 of these are

first attacks, and 185 000 are recurrent attacks [2]. Stroke is a global epidemic, a health problem not limited to Western or high-income countries. Actually, about 85% of all stroke deaths are registered in low- and middle-income countries, which also account for 87% of total losses due to stroke in terms of disability-adjusted life years [3]. Stroke incurs a huge burden to the society. The treatment and productivity losses due to death and disability from stroke lead to large societal costs and healthcare expenditure in many countries.

STROKE PREVALENCE AND INCIDENCE

The prevalence of stroke varies by sex and regions, partly due to different methods of estimation between studies [4]. A review of 23 data sources indicated stroke is becoming more common worldwide [5]. In developing countries, the stroke prevalence is increasing significantly. For example, the standardized stroke prevalence among Chinese adults aged 35 years old and above was 1111.5 per 100,000, yet the rate of urban residents (1544.8 per 100,000) was twice the rate of those living in rural areas (758.1 per 100,000) [6]. A study in Bangladesh involving 15627 participants aged 40 years and above found a higher stroke prevalence among men than women, the male to female ratio being 3.44:2.41 per 1000 [7], while twocommunity-based studies conducted in the Philippines reported a prevalence ranging from 1.9% to 6.5% [8]. In Vietnam, little data on stroke prevalence are available. A previous study conducted during 1994-1995 in the southern region of Vietnam reported an age-adjusted prevalence of 608 per 100,000 people, while mortality and incidence of the disease were estimated to be about 131 and 250 per 100,000 people, respectively [9].

MORBIDITY AND MORTALITY TREND

A systematic review showed a divergent, statistically significant trend in stroke incidence rates over the past four decades, with a 42% decrease in stroke incidence in high-income countries but a greater than 100% increase in stroke incidence in low to middle income countries. In 2000-2008, the overall stroke incidence rates in low to middle income countries have, for the first time, exceeded the level of stroke incidence seen in high-income countries by 20% [10]. During the past three decades, transition has taken place in many developing countries in terms of economy, demography, lifestyle, and health [11]. Non-communicable diseases (NCD) such as cardiovascular disease and stroke have emerged as leading causes of morbidity and mortality [12]. In Vietnam, rapid economic development and modernization have taken place since 1990's. Similar to other developing countries, Vietnam is also experiencing fast transition resulting in a widening gap between rich and poor people, degradation of the environment, an ageing population, and increasingly unhealthy lifestyles.

Consequently, Vietnam is now facing a “double burden” of old communicable diseases and emerging NCD. According to hospital statistics for the whole country, NCD admissions rose from 39% in 1986 to 65% in 1997 and cases of death from NCD increased from 42% in 1986 to 62% in 1997 [13]. Ischemic stroke was ranked number one among the leading causes of death [14].

RISK FACTORS OF STROKE

Stroke is not a single disease but a highly complex syndrome consisting of a group of heterogeneous disorders with many genetic and environmental risk factors [15, 16]. Risk factors for a first stroke are classified according to potential for modification (non-modifiable, modifiable, or potentially modifiable) and strength of evidence (well documented or less well documented) [17].

Non-Modifiable Risk Factors

Non-modifiable risk factors include age, gender, low birth weight, race/ethnicity, and genetic predisposition. In particular, gender plays an important role in the epidemiology of stroke. Worldwide, stroke is more common among men, but women are more severely ill. A review assessing 59 incidence studies from 19 countries and 5 continents claimed that male stroke incidence rate was 33% higher and stroke prevalence was 41% higher than those of the females, with large variations between age bands and between populations. However, stroke tends to be more severe in women, with a one-month case fatality of 24.7% compared to 19.7% for men [18].

Age is another well-known non-modifiable risk factor for stroke. In a prospective study, age at natural menopause before age 42 was associated with an increased ischemic stroke risk. Women with menopause before age 42 had twice the stroke risk compared to all other women [19].

On the other hand, studies on twins, family history and animal models [20-22] provide evidence for genetic contribution to the common forms of stroke, yet no major risk variants have been identified showing consistent results across populations.

Modifiable Risk Factors

There are many well-documented and modifiable risk factors for ischemic stroke. These include hypertension, exposure to cigarette smoke, alcohol consumption, diabetes, atrial fibrillation and certain other cardiac conditions, dyslipidemia, carotid artery stenosis, sickle cell disease, postmenopausal hormone therapy, poor diet, physical inactivity, and obesity and body fat distribution.

In relation to smoking, a study reported the relative risk increases from 1.16 for exposure to five cigarettes per day to 1.56 for exposure to 40 cigarettes per day. There is evidence of a strong, consistent and dose-dependent association between exposure to smoking and risk of stroke, suggestive of a causal relationship, with disproportionately high risk at low levels of cigarette smoking suggesting no safe lower limit of exposure [23].

For alcohol consumption, dose-response analysis revealed that the lowest risk of stroke mortality occurred with at most one standard drink per day. Secondary analysis of mortality from all causes showed lower risk for drinkers compared to non-drinkers. Consequently, light to moderate alcohol consumption is associated with a reduced risk of stroke [24].

An epidemiological survey in China found the stroke incidence significantly higher among individuals with atrial fibrillation (12.1%) compared with those without (2.1%) [25]. The prevalence of stroke in nonvalvularatrial fibrillation patients was 24.2%, and this rate increased dramatically with age [26]. For example, the prevalence of stroke was 4.3% in patients younger than 40 years of age but increased to 32.9% among atrial fibrillation patients 80 years of age or older. Therefore, atrial fibrillation is considered a major risk factor for ischemic stroke [26].

In relation to dietary pattern, a Chinese study concluded that the Western diet characterized by high consumptions of beef, fruit, egg, poultry, and seafood is associated with an elevated risk of stroke, but the associations become non-significant after adjustment for obesity, hypertension, hyperglycemia, and dyslipidemia [27]. Indeed, the combination of the four risk factors, namely, hypertension, diabetes, obesity and cigarette smoking, conferred the highest odds of having an cerebrovascular event [28].

Physical inactivity or a sedentary lifestyle also contributes to the stroke etiology. A recent large cohort study observed that moderate- to heavy-intensity physical activity, but not energy expended, is protective against ischemic stroke independent of other stroke risk factors in men [29].

It is known that treatment with cholesterol-lowering medications and changes in low-density lipoprotein cholesterol level over time may attenuate the stroke risk, while the role of lipids in the development of ischemic stroke has been less consistently observed [30].

Other modifiable risk factors for stroke examined in the literature include sleep duration [31], diabetes [32], exposure to antipsychotics [33], and low serum magnesium level [34]. In view of the large number of plausible risk factors, tackling any single lifestyle related factor is therefore not sufficient for the primary and secondary prevention of ischemic stroke [35].

PREVENTION STRATEGY IN VIETNAM

Stroke is a severely neglected problem in lower income countries such as Vietnam. Population-based epidemiological studies and stroke prevention programmes to inform and control stroke are urgently required. On the basis of successful experiences in cardiovascular disease, such studies should now be feasible in stroke [36].

In particular, large-scale epidemiological studies that utilise standardised approaches to measure risk factor exposures for each stroke subtypes are needed to understand the reasons for differences between regions and subpopulations, which have implications for the development of population-based prevention programmes. Large samples are also required in such studies to distinguish interactions between risk factors and exposures (e.g., between genes and environment).

Current approaches to primary preventive action emphasize the need to target the absolute risk of disease rather than individual risk factors. Lifestyle interventions serve as a basis for primary prevention of ischemic stroke. It is estimated that 70%of strokes are potentially preventable by lifestyle modification, but prospective evidence is required to support these hypotheses derived from epidemiological studies. Different strategies for drug interventions in primary prevention have been proposed, including the polypill strategy.

Based on the available evidence, additional preventive measures should focus on blood pressure, chronic heart failure, and possibly lipids [37].

In Vietnam, a study was conducted during 2001-2009 in the rural areas of Ba-Vi district, Ha-Tay province [38]. It concluded that alarming increases in risk factors in the general population warrant comprehensive multi-level prevention strategies. Both top down and bottom up approaches were applied to implement a hypertension management programme in the rural commune. The study demonstrated the feasibility, applicability and benefit of a community-based intervention in a low resource setting to engage all involved partners. This strategy should be incorporated as part of an integrated and coordinated national programme to prevent and control ischemic stroke [38].

CONCLUSION

Ischemic stroke is diversely reported by different countries and regions worldwide. Although a slight declining trend has been observed in the US and some European countries, in low and middle-income countries, the rate of ischemic stroke is increasing rapidly. There are multiple risk factors for stroke in these countries due to poor management and less effective control programmes. In Vietnam, epidemiological information about ischemic stroke for the population is currently lacking. Further studies are needed to provide evidence for the development of an effective prevention and control programme in the future.

ABSTRACT

Manipulation of the protein kinase C (PKC) signaling pathway has been recognized as a potential therapeutic target for numerous disease states, the most well-investigated being cardiovascular disease. Recent discoveries in preclinical models of neurologic disease ranging from Alzheimer's disease (AD) to traumatic brain injury (TBI) to stroke have identified changes in PKC expression and in some cases, successfully targeted this pathway therapeutically. The effects of altered PKC expression following injury remain under investigation with some studies implicating PKC in the regulation of oxidative stress, apoptosis, inflammation, and vascular remodeling. Additionally, various PKC isoforms may be involved in both beneficial and detrimental processes following injury as evident by the role of PKC in mediating neuroprotection following hypoxic preconditioning but also being associated with blood-brain barrier (BBB) disruption in other studies. Furthermore, preclinical studies of neurologic injury and disease often fail to emphasize the effect of aging, despite the fact that age is the greatest risk factor for numerous neurologic diseases such as stroke and AD. This is of particular relevance in

the regulation of PKC function as aging has been shown to alter enzyme translocation, thus altering function. This work reviews the location and pathways associated with various PKC isoforms, the role of PKC isoforms in the aging process, as well as implications of PKC signaling following neurologic or cerebrovascular injury. We provide insight into potential downstream pathways of interest and the potential role of PKC modulation as a therapeutic target for ischemic stroke based on findings in not only preclinical studies of stroke but also studies of other neurologic and cardiovascular diseases.

INTRODUCTION

PKC Isoforms – A Lesson in Structure-Function Relationships

The PKC family is a series of threonine/serine kinases. Up to twelve different isoforms exist each with their own actions and specific pathways of activation. All isoforms are present in some form or another within the brain [1]. These isoforms have been grouped into three classifications: conventional, novel, and atypical. The classification is based on the unique polypeptide chains and the cofactors associated with each group. The NH₂-domain is specific for the membrane phospholipids that interact with PKC during translocation.

Figure 1. Schematic of typical protein sequence for PKC showing the variations between conventional, novel, and atypical subgroups. cPKC requires diacylglycerol, phorbol ester, and calcium for activation. nPKC requires diacylglycerol and phorbol ester but not calcium for activation. aPKC is not dependent on diacylglycerol or phorbol ester but activates quicker in their presence which is represented by the black lines.

The COOH-domain is specific for the activating cofactors, and the C2 domain has binding capacity for receptors for activated C kinases (RACKs). Conventional isoforms (cPKC α , - β I, - β II, and γ) require calcium, phosphatidylserine (PS), and diacylglycerol (DAG) for activation. The novel isoforms (nPKC δ , - ϵ , - η , - θ , and - μ) require PS and DAG but not calcium.

The atypical isoforms (aPKC ζ , - λ) are unresponsive to DAG, PS, and calcium (Figure 1). Both cPKCs and nPKCs activate the extracellular signal-regulated kinase (ERK) and mitogen-activated protein kinase (MAPK) cascade among other pathways [2]. These pathways will be discussed in detail in later sections.

In investigating PKCs, it was discovered that a panel of nine genes express the phospholipid-kinases. These genes produce the PKCs in various tissues throughout the body and account for their broad distribution and functions. PKC γ , PKC δ , PKC α , and PKC ϵ are the most predominant isoforms associated with neurologic diseases. Other isoforms play more predominant roles in other organ systems such as the heart.

Expression of PKC Isoforms – Systemic and Cellular Considerations

PKCs have been found in a large number of organs such as the heart, brain, lungs, kidneys, and organs of the gastrointestinal tract as well as in cells of the hematopoietic system [3-6]. Different isoforms are located in a tissue-specific manner. PKC α is highly expressed in β cells of the pancreas, but has also been linked to pathological tissue such as breast cancer and malignant gliomas [7]. PKC γ is endogenous to the α cells in the pancreas. PKC ζ has been linked to matrix metalloproteinase (MMP) regulation in smooth muscle cells [8]. PKC δ is upregulated in endothelial cells following ischemia [9]. PKC ϵ is present in large quantities in the hippocampus and olfactory tubercle [10]. PKC β II is present in both normal and pathological B-cells [11]. Other isoforms such as PKC θ and PKC α work together and have important roles in T-cell regulation and IL-2 activation [12]. All PKCs are originally localized in the cytosol of specific cells and must undergo a translocation to a membranous site. Depending on the isoform or tissue, this membranous site could be the nucleus, golgi apparatus, endoplasmic reticulum, mitochondria, or even the cell membrane [13, 14].

Activation of PKC Isoforms

PKCs are completely phosphorylated following translation but are inactive due to pseudosubstrate interference with the binding domain. The pseudosubstrate domain keeps the PKC polypeptide in a folded configuration. PKCs are localized in the cytosol of specific cells and must be activated by removing the pseudosubstrate domain. After activation, PKCs must then be translocated to membranous sites in order to phosphorylate downstream pathways [15]. Lipopolysaccharide (LPS) in the presence of the aforementioned endogenous cofactors (DAG, Ca⁺⁺, and PS) induces activation of PKC β , - ϵ , and - ζ [16]. Phorbol esters such as tissue plasminogen activator (TPA) and even the β -adrenergic system have also been shown to activate PKCs [17]. A variety of growth factor receptors can activate PKCs as well. The increase in growth factors during cancer is one of the reasons PKCs have become ideal targets for therapeutic interventions [18]. Once activated, PKCs can be translocated. The

translocation mechanism is initiated through PKC binding with RACKs. RACKs are 30-36 kilo-Dalton proteins that are located in cytoskeletal compartments. They interact with a C2 domain on the PKC polypeptide and thus do not interfere with the substrates binding site. Each isoform of PKC has a specific RACK. RACKs also have other functions besides binding PKCs such as anchoring phosphodiesterase and integrin, and contributing to vesicle release and cell-to-cell communication [19, 20].

After PKC binds to its isoform specific RACK, the entire unit will translocate from the cytoplasm to the membranous sites previously mentioned.

Regulating PKC Activation

In general, PKCs are self-regulated proteins. When PKCs are activated, the pseudosubstrate dissociates. Eventually, the PKC loses one of its three phosphate groups at a site known as the activation loop. When this occurs, the cofactor separates from the active site and the PKC is no longer functionally active.

The pseudosubstrate reattaches and the PKC is in its inactive state. In order for the PKC to return to a state where it can activate again, it must regain the phosphate group that it has lost. A phosphoinositide-dependent kinase 1 (PDK-1) phosphorylates the PKC at the activation loop. This additional phosphorylation causes the other remaining phosphate groups to reconfigure and realign. In some PKCs, PDK-1 does not directly phosphorylate the activation loop but instead induces autophosphorylation. Once all phosphate groups have been restored and the other phosphate groups have been reconfigured, the PKC can undergo activation [21].

PKC – A Role in Disease Processes?

PKCs typically regulate important functions such as cell growth and differentiation, secretion of hormones, and normal membrane functioning. They also play a key role in the regulation of the Na/K/2Cl-cotransporter (NKCC) and neuronal sodium and potassium transport. Several of the PKC isoforms contribute to the pathology of neurologic and cardiovascular disease sometimes in direct contrast to one another. In stroke, the PKC isoforms α , β I, and ϵ contribute to the activation of NKCC at the blood-brain-barrier (BBB). This leads to the protectant mechanism of increased K^+ transport across endothelial cells and an increased K^+ flow back into the blood stream [22]. PKC β I also acts as a neuroprotectant for astrocytes by inducing phosphorylation and increasing the activation of excitatory neurotransmitter transporters. Similarly, PKC α acts as a neuroprotectant for neurons by activating the adenosine signaling pathway [23]. In contrast to these neuroprotectant roles, PKC δ in conjunction with amplified Ca^{++} influx has been shown to cause increased constriction of the middle cerebral artery (MCA) prior to and during ischemic stroke [9, 24]. Following ischemia, PKC β II has been linked to increased endothelial permeability and inflammation [25]. Stroke is not the only neurologic disease where PKCs are active.

The isoform PKC δ also regulates mitochondrial-induced apoptosis and has been linked to diseases such as Alzheimer's disease (AD), Parkinson's disease (PD), Amyotrophic Lateral

Sclerosis (ALS), and Traumatic Brain Injury (TBI) [26-29]. PKC δ is cleaved by caspase-3 and translocates to specific cells via the appropriate RACK. It then enters the mitochondria of these target cells, and eventually phosphorylates a series of enzymes such as the GTPase Drp1.

This signaling cascade ultimately leads to mitochondrial-mediated apoptosis [30]. PKCs also play a critical role in cardiovascular disease. PKC ϵ provides cardioprotection through activation of mitochondrial aldehyde dehydrogenase 2 (ALDH2). PKC ϵ is originally found in the cytosol and translocates to the cell particulate fraction following hypoxia preconditioning. In addition to an interaction with the appropriate RACK, PKC ϵ associates with heat shock protein 90 (HSP90) before it translocates [31]. Similar to the brain, PKC δ leads to reperfusion injury following the initial onset of myocardial infarction. Importantly, cardiovascular-based studies have revealed an increase in PKC translocation by over 50% following injury. When inhibited, injury is significantly reduced through attenuation of the pro-apoptotic pathway in mitochondria [32].

If an animal is pre-conditioned to ischemia before injury, the protectant isoform PKC ϵ will be upregulated and the harmful isoform PKC δ will be downregulated [33, 34]. As more is discovered about PKCs, it is becoming increasingly apparent that they have important functions in a broad spectrum of diseases.

This is particularly true when considering the greatest risk factor for the development of neurologic disease is aging. Since age in and of itself alters the dynamics of PKC signaling, it is important to realize that unique modifications occur in aged animals even before the onset of disease [35].

EFFECT OF NEURAL DISEASE AND INJURY ON PKC ACTIVITY

Numerous disease states, both neurologic and non-neurologic in nature, have been associated with changes in both PKC isozyme activity and translocation. The following sections highlight the role of common neurologic disease states in modulation of PKC activity but it's important to consider that much of what is known concerning the role of PKC in pathophysiology is derived from work in other organ systems, namely cardiovascular.

Many comprehensive reviews focusing on the general role and effects of PKC following injury, as well as specific isozyme-mediated effects, have been published by the Mochly-Rosen group and others, often in reference to cardiovascular disease, a disease process that likely shares many similarities with cerebral ischemia. As such, the cardiovascular literature and the aforementioned reviews provide insight into the role of PKC in neural injury and can serve as further reference for material not covered herein [36].

The interest in PKC isozyme modulation following neurologic injury appears warranted due to the identification of deficits and abnormalities in PKC-mediated signaling cascades, particularly in relation to learning and memory deficits, in the brain that occur acutely in patients with Alzheimer's disease and/or ischemic stroke [37]. Of particular interest is the role of the epsilon izoyme as PKC ϵ is expressed more highly in the brain than most other tissue, suggesting a critical role in nervous system homeostasis. This notion is consistent with the role of PKC ϵ in various functions including perhaps most notably, neurotransmitter release and ion channel function [10]. Furthermore, contrasting viewpoints concerning the effect of

neural injury on PKC activity exist and therefore, additional investigation is required to understand both these effects and how PKC can be manipulated pharmacologically for therapeutic benefit [3].

Alzheimer's Disease (AD)

Of the neurologic disease states in which PKC has been investigated in relationship to disease pathophysiology, AD comprises the vast majority of reported studies. Importantly, deficient PKC isozyme function has been described as a key component of disease pathogenesis and consequently raised the prospect of PKC as a promising therapeutic target [38]. Pathologic studies conducted on the brains of AD patients reveal a close correlation between dementia and synaptic loss. The precise mechanisms leading to synaptic loss have been poorly elucidated until recent work of Hongpaisan, et al. in which a reduction in synaptogenic PKC isozymes, particularly α and ϵ , and associated substrates was found to occur in conjunction with increased soluble beta amyloid but prior to both plaque development and corresponding neuronal loss. These findings were consistent with clinical autopsy results in which age-matched, non-demented control patients exhibited a higher level of PKC expression and activity in comparison to patients afflicted with AD [39].

Mechanistic studies have revealed a role for PKC activation in activation of α -secretase, an enzyme responsible for converting amyloid precursor protein (APP) to soluble sAPP α , potentially preventing amyloid beta (A β) production. Besides altering production of A β , PKC-mediated pathways have been reported to increase the degradation of A β , further altering the ratio of production and degradation in a beneficial manner [40]. In addition to providing a potential therapeutic approach to AD, these studies have also demonstrated clear roles for many PKC isozymes in learning and memory-associated tasks that are affected in many neurologic disease states such as ischemia and traumatic brain injury [38].

Ischemia

Conflicting evidence exists concerning the effect of ischemia on PKC expression and activity [2, 3, 25, 41, 42]. This is thoroughly reviewed by Bright and colleagues and perhaps most importantly, only recently have the effects of various isozymes been recognized as frequently divergent, necessitating the consideration of disease-isozyme relationships rather than consideration of PKC activity/expression as a whole [1]. We attempt to identify these often different, if not opposing, roles of various isozymes as related to disease pathophysiology and therapeutic development in the remainder of this work.

In addition to consideration of potentially contrasting isozyme effects, the impact of preclinical model and corresponding severity of ischemia has often gone unrecognized. Importantly, Sun and colleagues investigated this precise issue, demonstrating that while PKC activity is increased with mild ischemia, severe ischemia results in diminished PKC activity [37]. Besides severity of ischemia, the location of both ischemia and sample must be taken into account. Cortical and striatal tissue may respond differently to ischemia due to unique metabolic demands and cellular composition. Whether tissue samples analyzed are from

infarct core or penumbral regions may further influence PKC-related findings [43]. Other factors to consider include the time of analysis post-onset of ischemia, the role of isozyme phosphorylation in activation and downstream-signaling, and discrepancies between *in vitro* and *in vivo* studies. Contrasting results between cell-based and animal-based studies, as reported by Fleegal and colleagues, indicate the potential for cell-specific effects, further complicating the study of PKC-mediated pathways [25]. Whether manipulation of PKC in response to injury has similar effects across the various cell-types found within the brain remains to be seen.

Regardless of the aforementioned issues in comparing results across studies, it is clear that PKC is involved in both the initial, acute response to ischemia as well as more delayed effects throughout the subacute and chronic periods. This is consistent with work showing PKC δ increased throughout both infarct core and penumbra regions [37]. Likewise, PKC ϵ has been shown to be up-regulated rapidly following onset of ischemia and remains elevated in both *in vitro* and *in vivo* studies [2, 44]. Most importantly, preclinical studies targeting specific PKC isozymes using either pharmacologic agents or genetic modifications have demonstrated the ability to reduce cerebral injury [1, 45, 46].

Ischemic Preconditioning

In addition to the effect of ischemia on PKC and modulation of PKC for therapeutic benefit discussed above, PKC is also involved in the beneficial effects associated with ischemic preconditioning [10, 37, 47]. Historically, the PKC ϵ isozyme has been most frequently recognized as essential in ischemic preconditioning [10, 37, 48]. The protective effects associated with PKC ϵ activation that occurs with preconditioning have been ascribed to the role of PKC ϵ in the adenosine/NMDA-activated signal transduction pathway [37]. Recent work in mice undergoing hypoxic preconditioning (HPC) prior to middle cerebral artery occlusion (MCAO) has implicated PKC β II.

This finding is consistent with observed increases in PKC β II membrane translocation in the acute phase of HPC, but further work remains to clearly elucidate the mechanism of protection [47, 48]. Other isozymes such as PKC δ , a pro-apoptotic kinase, have been identified as being decreased with HPC in cardiac tissue, which may lead to the protective effects associated with HPC [34].

Traumatic Brain Injury

Relatively little work has been done investigating the effect of TBI on PKC activity with the exception of that by Yang and colleagues and Zohar and colleagues. Yang, et al. demonstrated significant changes in PKC activity at 1 and 3 hours after TBI but not at 5 minutes or 24 hours post-injury. At the 3 hour time point, PKC translocation to membrane fractions was elevated [3]. While Zohar, et al. did not assess activity or translocation, administration of bryostatin-1, a potent PKC activator, resulted in diminished learning and memory deficits following TBI. The reduction in learning and memory deficits was consistent

with improved maintenance of synapses as evident by pre-synaptic synaptophysin and post-synaptic spinophylin immunohistochemistry [27].

ROLE OF PKC IN NEURAL INJURY OUTCOME

The effect of altered PKC activity observed in many of the aforementioned neurologic disease and injury states has not been entirely elucidated but many recent works have tied various PKC isozymes to oxidative stress, regulation of apoptosis, blood-brain barrier (BBB) breakdown, and processes associated with recovery/repair. In the following sections we expand upon work investigating the role of PKC in these disease-associated events by again linking work completed across multiple organ systems, mainly neurologic and cardiovascular.

Modulation of Response to Oxidative Stress

Oxidative stress has frequently been cited as a potentially precipitating factor in many pathologic states, particularly those associated with the aging process resulting in the theory of ‘inflammaging’ [49]. A reduction or loss of PKC activity has previously been correlated with injury severity but how PKC modulated this response was unclear. Emerging evidence implicates PKC in the modulation of oxidative stress-induced apoptosis, generation of oxidative stress through NADPH oxidase, and mitochondrial function.

Oxidative stress leads to PKC δ translocation to the mitochondria, termed mitochondrial targeting, ultimately causing loss of mitochondrial transmembrane potential and release of cytochrome c that leads to apoptosis [32, 50]. PKC δ also appears to be somewhat unique in the response to oxidative stress in that it may also further amplify the apoptotic cascade via caspase activation and subsequent feedback [51]. Importantly, previous work has shown these processes can be inhibited using PKC δ inhibitors [50, 52]. These inhibitors may also prevent upregulation of NOX1, part of the NADPH oxidase complex, via PKC δ that contributes to oxidative stress and has been identified previously as a potential therapeutic target [53-55].

Effect of PKC on Cell Survival

Consistent with divergent effects of PKC isozymes on other cellular functions, PKC isozymes have been characterized as pro- or anti-apoptotic in nature. Consequently, work utilizing non-specific PKC modulators has shown both protective and deleterious effects in response to injury, likely due to isozyme-specific effects [56]. PKC isozymes identified as suppressing apoptosis include α , β , ϵ , and ζ while those acting as pro-apoptotic are δ and θ .³⁷ Most work investigating PKC-mediated effects on cell survival, namely apoptosis, has centered on the role of PKC δ and PKC ϵ .

Inhibition of PKC δ has been found to be universally protective regardless of organ system following onset of ischemia as evident by diminished pathologic features of apoptotic processes such as DNA laddering and fragmentation [32, 57]. Similarly, proteins involved in apoptotic signaling cascades such as cytochrome c, caspase 3, and Bcl-2 associated death

protein (BAD) were reduced following inhibition [32, 57-60]. Perhaps most importantly, at least from a therapeutic development standpoint, is that administration of PKC δ inhibitors results in improved outcome following ischemic stroke, even when administered up to 6 hours after onset [58].

How exactly PKC δ mediates the aforementioned effects remains to be clearly elucidated but numerous pathways have been proposed in which glycogen synthase kinase-3B (GSK-3B) and Akt signaling pathways are altered [57, 58]. Others have shown a role for Drp1, a mitochondrial fission protein to which PKC δ binds, that is phosphorylated upon binding resulting in enhanced mitochondrial fragmentation [59]. Furthermore, PKC δ may be partially responsible for mediating the protective effects of hypothermia following ischemia [41].

Investigation of PKC ϵ is more limited and the effects not as clearly elucidated as those associated with PKC δ modulation. Bright and colleagues demonstrated a protective role of $\psi\epsilon$ RACK and associated PKC ϵ -mediated effects when activator peptide is administered near the time of stroke onset, implicating PKC ϵ in acute pathophysiologic events. When given 24 hours before ischemia or at the onset of reperfusion, $\psi\epsilon$ RACK-mediated activation did not improve nor worsen outcome [44]. In other work, activation of PKC ϵ restores the phosphorylation state of endothelial nitric oxide synthase (eNOS), increasing cell survival [61].

Regulating BBB Integrity Through Matrix Remodeling

Neural injury and degeneration often involves transient periods of blood-brain barrier (BBB) disruption. Improving the maintenance of BBB integrity has been identified as a promising therapeutic target for neurologic disease, particularly ischemic stroke. Much of the previous work into mechanism of BBB breakdown after injury has focused on the role matrix metalloproteinases (MMPs) play in both acute breakdown, associated with deleterious processes, as well as chronic regulation required for recovery/repair. While regulation of MMP activity has largely remained unclear and complicated, emerging evidence indicates a clear role for PKC signaling. Fleegal and colleagues have shown that PKC inhibition with chelerythrine chloride reduces BBB permeability, which lends credence to the idea that PKC may control expression and function of junctional proteins [25]. This is consistent with the suggestion that PKC may regulate other junctional proteins associated with the epithelial barrier [62].

The attempt to identify the role of specific isozymes involved in BBB permeability has produced multiple candidates depending on the model used, time points, and severity of injury utilized. In a global ischemia model, analysis of cortical microvessels demonstrated changes in PKC distribution, particularly that of PKC θ and PKC ζ , as well as phosphorylation activity of these isozymes. This suggests that these signaling molecules may further mediate tight-junction strength [63]. Others have suggested a role for PKC ζ in MMP regulation as well with Hussain and colleagues showing that PKC ζ activity is required for cytokine-induced activation of MMP-1, -3, and -9 [8].

Other isozymes identified as contributing to BBB regulation include PKC δ and PKC ϵ [62, 64, 65]. Notably, some proposed neuroprotective agents, such as doxycycline, have

reduced BBB breakdown and improved neurologic outcome while downregulating PKC δ , suggesting protective effects may be mediated via PKC isozyme modulation [66].

How PKC activation and translocation leads to MMP activation is not well elucidated but indications are that it may involve downstream signaling cascades mediated through the NF- κ B or MAP/ERK pathways [67, 68]. Work in other organs such as the kidney has shown other pathways and molecules may be involved in regulating MMP gene expression such as c-Fos and c-Jun, two cellular proto-oncogenes [68]. Other studies indicate potential modulation of cytokine-induced effects on MMP expression by PKC isozymes as well as identify a possible role of PKC-mediated phosphorylation of MMP-2 that then alters the activity of the protease [69-71].

In addition to the role the BBB serves in regulating solute passage and preventing vascular dysfunction, it also is responsible for maintaining the immunoprivileged state. PKC δ activation in endothelial cells studied *in vitro* revealed diminished neutrophil migration following stimulation with leukotriene B4 (LTB4) or tissue necrosis factor- α (TNF- α) without altering endothelial barrier integrity [72]. This would appear to be in contrast with previous findings in which PKC δ inhibition reduces endothelial dysfunction and improves BBB integrity [9, 59, 73].

Role in Recovery and Repair Following Neural Injury

Understanding the mechanisms associated with recovery and repair from neural injury remains the subject of intense investigation due to the potential promise for therapeutic development for a number of neurologic disease states ranging from ischemic stroke to TBI. Recovery/repair involves a complex array of simultaneously occurring processes including neural migration and angiogenesis. Recent work highlights roles for PKC-mediated signaling in each of these repair-associated components.

One of the greatest challenges in recovery/repair events is overcoming inhibitory activity attributed to the glial scar found at the lesion site. Much of the inhibition resulting from myelin and other molecules composing the glial scar is regulated by cPKC activity. By blocking PKC activity, neurite outgrowth has been stimulated both *in vitro* and *in vivo* despite the normally prohibitive presence of myelin [37]. This process likely requires a series of protease and metalloprotease-mediated steps, which may be regulated by PKC as discussed above. A prime example is that of semaphorin 3A (Sema3A), a guidance molecule that activates MMP-2 in a PKC α -dependent fashion [74]. Besides involvement in axonal guidance, PKC activation using bryostatin has been shown to increase mushroom spine number on neurons in a memory-specific manner [75].

Actual neurite outgrowth has been shown to be PKC ϵ -dependent in nature with an increase in PKC ϵ promoting nerve growth factor-induced growth whereas a decrease inhibits the process [10]. This overall pro-repair event appears consistent with work completed in the cardiovascular system in which sustained PKC ϵ inhibition following heart failure prolonged survival while reducing dysfunction through a variety of mechanisms, many of which are associated with the regulation of inflammatory pathways and inflammatory cell migration [14]. PKC δ , often thought of in a negative light with regards to impact on neural injury in the acute period, has been shown to modulate critical aspects of repair/regeneration such as

angiogenesis and cell cycle modulators, making PKC δ activation potentially beneficial in the chronic period post-injury. Specifically, Kim and colleagues demonstrated that PKC δ activation promotes NADPH oxidase activity and increases HIF-1 α levels, leading to angiogenesis [76]. PKC δ is also involved in cell cycle events based on actions on Cdk5 via p35 and consequently regulates cortical radial migration of neurons [77].

Effect of PKC Modulation on Learning and Memory

In addition to the role of PKC in neural migration and repair following injury, the effect of PKC on learning and memory has been well established in both healthy and injured animals. In *Hermisenda*, bryostatin was found to enhance memory acquisition at low-doses consistent with up-regulation of specific PKC isozymes but at high doses, bryostatin resulted in down-regulation and no recall of the associative training task [78]. One of the major cellular mechanisms associated with learning and memory, long-term potentiation (LTP), seems to require PKC-mediated signaling based on previous findings assessing the effect of phorbol esters and PKC inhibitors on LTP. While PKC has been described as necessary, but not sufficient, to induce LTP, it is clear that PKC isozymes such as PKC ϵ contribute to presynaptic control [10]. Furthermore, PKC modulators such as bryostatin have been shown to induce synthesis of proteins associated with memory consolidation, a fact that makes PKC modulators a potentially promising therapeutic target for conditions associated with memory impairment like Alzheimer's disease [79].

STUDYING PKC ISOFORM-SPECIFIC EVENTS: USING AVAILABLE TOOLS

Work in other organ systems, such as the cardiovascular system, has illustrated the importance of elucidating isozyme-specific events for the development of therapeutic agents. For example, Chen and colleagues showed that various isozymes may have similar effects with regard to one cellular function and opposing effects on another function, explaining contrasting findings often reported due to use of non-isozyme selective pharmacologic agents. Furthermore, the isozyme-dependence of cellular functions is of particular interest considering the elevation of multiple isozymes following injury and the idea that it is the balance struck between various isozymes that determine the overall outcome post-injury [33].

The elucidation of isozyme-specific events can be accomplished via genetic manipulations such as knockouts or through the use of pharmacologic inhibitors. Of the isozymes identified, at least four have been successfully mutated to produce null mice. This includes the γ , β , ϵ , and θ isozymes.

While null mice may provide insight into neurologic effects associated with a respective isozyme, animals are affected systemically as evidenced by β and θ -null mice, which have shown phenotypes consistent with immunologic changes [80]. One of the advantages of null mice though is the ability to target a given isozyme specifically, a significant challenge observed in studies using pharmacologic inhibitors that often inhibit one isoform class rather than a specific isozyme. For example, Go6976 has been described as inhibiting classical Ca²⁺-

dependent isozymes whereas Go6850 inhibits both conventional and novel isozymes [62, 74]. Other agents such as Ro 31-8220 have been shown to inhibit PKC α more selectively at low concentrations than high concentrations where additional PKC isozymes may be affected [75].

More recently, isozyme specific inhibitors have become available as well as the development of peptide-based specific inhibitors [1, 39, 57]. In addition to inhibitors of PKC, activators are also available and include promising therapeutic candidates, such as bryostatin, for a host of neurologic disorders [27, 39, 45].

FUTURE DIRECTIONS

Modulation of PKC using isozyme-specific pharmacologic and peptide-based inhibitors has yielded positive results in many preclinical studies, particularly in models of neurologic diseases such as stroke, TBI, and AD. Despite the apparent success of these studies and progression to early phase clinical trials in some cases, further studies are required to elucidate effects of common disease comorbidities such as aging, hypertension, and diabetes that have not been addressed in early preclinical studies. Similarly, many of the early preclinical studies have been conducted *in vitro* on neurons and have not addressed the potential of cell-specific or time-dependent effects. Furthermore, investigating signaling mechanisms associated with beneficial and detrimental PKC-mediated effects may lead to optimal therapeutic development by regulating multiple isozymes.

Alterations in PKC-Mediated Signaling Associated with Aging

The greatest risk factor for neurologic diseases such as ischemic stroke and AD is age. Most preclinical studies investigating PKC-mediated effects have not considered the role of age and the aging process. In one study that did address the effect of age on PKC in the brain demonstrated that cPKCs are substantially down-regulated in the cortex, striatum, and hippocampus of middle-aged animals compared to young animals. This down-regulation drastically changes the expression of substrates normally modulated by PKCs such as nitric oxide synthase (NOS) [61, 81]. Ultimately, such age-related alterations might predispose the brain to Alzheimer's disease, dementia, or other memory dysfunctions. In addition to PKC downregulation, the availability of the remaining PKC isoforms is disrupted. Most isoforms are not present in membranous regions due to a deficit in translocation. RACKs have decreased expression, up to 50%, in the aged brain. Without RACKs, PKCs are isolated to the cytosol of cells and cannot translocate even if activated. This leads to deficits in PKC-mediated neuronal plasticity and subsequent loss of LTP [13, 82]. To further complicate matters, oxidative stress and aluminum-induced neurotoxicity can cause PKC to transfer from the plasma membranes to the cytosol in aged brains [83]. In other tissues such as the heart, some RACKs may be functional while others are not. When an aged heart is confronted with increased preload, the expression of most PKCs is up-regulated. The RACKs specific for PKC β and PKC ϵ are still functional and can therefore initiate translocation. Since PKC β and PKC ϵ are overactive compared to the other regulatory cytosol-bound PKCs, the heart

hypertrophies and becomes fibrotic [36]. Considering the potential effect of age on RACK functionality, the ideal therapeutic would not depend on RACK function to mediate therapeutic effects on the targeted isozyme. Several drugs have been designed for such targets, and one specific drug of interest is Bryostatin-1. Bryostatin-1 is a potent activator of PKCs and also aids in increased translocation of PKC α [38, 78]. Kostyak and colleagues demonstrated that at baseline, PKC δ levels in the mitochondria of the heart were increased by approximately 40% in comparison to the normal adult heart. Similarly, aged hearts contained a nearly 2-fold increase in cytosolic PKC δ in comparison to adult heart. Perhaps most importantly, inhibition of PKC δ with KID1-1 reduced the increased infarct volume typically found in aged hearts to a level more consistent with the adult heart [57].

Elucidating Cell-Specific and Time-Dependent Events

Investigating the pathophysiology of neurologic diseases such as ischemic stroke, as well as developing therapeutics, is complicated by the numerous cell-types required for both normal homeostasis as well as the response to injury and subsequent repair/recovery. Being that each cell-type may respond differently to injury, or at least exhibit varying sensitivity to injury, may necessitate investigation of PKC-mediated processes independently for targeted therapeutic delivery. This idea is consistent with the varied findings across cell-types such as the role of PKC in modulating the inflammatory process and microglial adhesion, astrocytic control of MMP-9, and oxidative stress in neurons [52, 67, 72, 84]. Besides cell-specific events, previous work has shown time-dependent changes in PKC-mediated signaling in cerebrovascular studies. For example, PKC δ is activated early in cerebrovascular events and likely plays a greater role in the acute period whereas PKC α may play a larger role in the chronic period after injury. Therefore, studies more adequately addressing the timing of isozyme increases or decreases following an injurious event may lead to more appropriate therapeutic development [85].

Understanding PKC-Mediated Pathways

PKC-mediated signaling is involved in a wide array of homeostasis-associated pathways as well as those that occur in response to injury, but how precisely many cellular effects are controlled through PKC activity remains unclear. Numerous pathways have been implicated based on work in the brain as well as cardiovascular systems, but how these pathways all interact, and the role of various PKC isozymes in these pathways, remains to be seen. One signaling molecule of interest is glycogen synthase kinase 3 beta (GSK-3 β), an enzyme responsible for phosphorylating glycogen synthase kinase (GSK). Aging has been recognized as altering the ratio between phosphorylated GSK-3 β and GSK-3 β , a difference that coincides with worsened cardiovascular injury in aged subjects. Reperfusion results in a worsening of this ratio in the mitochondria of aged hearts, an effect prevented by PKC δ inhibition [57]. Vascular endothelial growth factor (VEGF) appears to exert its mitogenic and permeability-associated effects via PKC β demonstrating another potential pathway of investigation [86]. Lastly, the protein kinase Akt, which has been identified as regulating apoptotic events, has

been shown to correlate with PKC δ activity in the acute period after ischemia but not after reperfusion [58]. This indicates a potential link between the two pathways but also demonstrates the inherent complexity of signaling cascades, particularly those that overlap or display time-dependent effects.

CONCLUSION

PKC clearly plays a role in neurologic injury and represents a promising therapeutic target based on work in numerous preclinical models of AD, ischemic stroke, and TBI. Activity of some PKC isozymes has been demonstrated in both clinical samples and preclinical studies at a variety of time points post-injury, likely in an isozyme-specific fashion. While the precise mechanism through which PKC isozymes influences outcome following injury is unclear, evidence indicates a role for PKC in regulating apoptosis, blood-brain barrier integrity, inflammatory cell adhesion/migration, and multiple aspects of recovery/repair (Figure 2).

Figure 2. Schematic demonstrating generic PKC activation processes and subsequent isozymes with identified functions in neural injury/repair. Each isozyme likely has time-dependent and isozyme-specific actions that contribute to a range of cellular effects both during normal homeostasis as well as in response to injury.

Understanding isozyme-specific functions and how to most appropriately target these effects remains under investigation but recent improvements in peptide-based inhibitors provides promise in more clearly elucidating the role of a given isoform over time. As progress continues in this regard, successful therapeutics in preclinical studies that have progressed to clinical trials, such as Bryostatins-1, may potentially be used to carefully target individual isoforms and likewise increase functional recovery following a variety of neurologic injury types.

Chapter 5

ROLE OF TRANSCRANIAL DOPPLER ULTRASONOGRAPHY IN CEREBROVASCULAR DISEASE

*Aftab Ahmad and Vijay K. Sharma**

Division of Neurology, National University Hospital, Singapore

ABSTRACT

Transcranial Doppler ultrasonography (TCD) is the only non-invasive diagnostic technique for obtaining reliable information about intracranial blood flow patterns in real-time. The information obtained from TCD often adds physiological component to the anatomical information obtained from other neuroimaging studies. TCD is relatively cheap, can be performed bedside for acute stroke patients as well as for patients with fixed vascular steno-occlusive disease. Some of the advanced applications of TCD include sonothrombolysis in acute ischemic stroke, monitoring for spontaneous emboli, right-to-left shunt detection and vasomotor reactivity, evaluation of vasospasm in patients with subarachnoid hemorrhage etc. These applications help in evaluating various stroke mechanisms, management plan as well as for prognostication purposes. TCD has been suggested as an essential ingredient of a comprehensive stroke center.

Keywords: Ischemic stroke, cerebrovascular disease, transcranial Doppler, cerebrovascular ultrasound

INTRODUCTION

Transcranial Doppler ultrasonography (TCD) is the diagnostic modality that provides the real-time information about various patterns of blood flow in major intracranial arteries in real-time. It was discovered for human use for measuring blood flow velocities in the middle

cerebral artery (MCA) in patients with subarachnoid hemorrhage (SAH) [1]. Over past 3 decades, the clinical and research uses of TCD have extended immensely. In acute stroke patients, TCD can be used for a rapid bedside diagnosis of intracranial arterial occlusion as well as for monitoring the effect of various therapeutic approaches to achieve recanalization. Importantly, continuous monitoring of the intracranial occlusions in acute ischemic stroke patients during systemic thrombolysis is known to improve the chances of recanalization. The advanced applications of TCD such as right-to-left shunt detection, vasomotor reactivity testing, and emboli detection serve as important tools in the armamentarium of stroke neurologists for understanding the etiopathogenic mechanisms in acute stroke and individualizing the treatment strategies.

TCD has been demonstrated to be reliable, if performed by experienced sonographers [2, 3]. However, the results match favorably only when the TCD study is performed in close temporal relationship to various contrast angiographic studies [4, 5]. Furthermore, TCD is comparatively cheaper diagnostic technique that can be performed bedside and allows prolonged monitoring capabilities in selected cases.

FAST TRACK INSONATION PROTOCOL

In patients presenting with acute ischemic stroke ‘time is brain’. For patients considered eligible for intravenous thrombolysis, rapid performance of TCD is essential. Accordingly, a fast track insonation protocol was developed for such emergency situations [6].

‘Fast-track’ evaluation of the cerebral circulation requires an experienced sonographer. Clinical presentations in acute ischemic stroke often determine the insonation steps in this protocol. Therefore, for patients presenting with right-sided symptoms, the insonation begins with insonation of the right middle cerebral artery (MCA) (presumed to be normal and unaffected) side. This step helps the sonographer in assessing the quality of temporal acoustic window in addition to visualizing the normal spectral flow pattern and velocity profile of the index patient. This is followed by insonating the MCA on the affected side, starting at the mid-M1-MCA depth range of 50-58 mm. In patients with a normal MCA flow, distal MCA segments are evaluated followed by ICA bifurcation. Absence of MCA flow signals due to arterial occlusion can also be confirmed by deeper insonation across the midline from the contralateral window. Flow direction and pulsatility is determined in the ophthalmic artery (OA) via transorbital window on the affected side at depths of 50-58 mm followed by deeper insonation (60-64 mm) of ICA siphon. Basilar artery (BA) is insonated next to determine if compensatory flow patterns. Insonation of vertebral arteries (VA), OA, and ICA on the non-affected side, as well as posterior cerebral arteries, is performed whenever the sonographer finds time during the course of prolonged monitoring. The ‘fast-track’ protocol allows the sonographer to complete the evaluation of cerebral hemodynamics within few minutes and does not affect neurological examination, setting of intravenous access. This protocol does not contribute to any time delays in initiating the thrombolytic therapy in acute ischemic stroke.

The yield of fast-track TCD protocol can be further enhanced by combining it with cervical duplex sonography of the carotid and vertebral arteries and detect the lesions amenable to interventional treatment (LAIT) [7], defined as occlusion, near-occlusion, $\geq 50\%$

stenosis or thrombi in an artery supplying brain area. The sensitivity, specificity, positive and negative predictive values for TCD in diagnosing LAIT are 96%, 75%, 96% and 75% respectively. The corresponding values for carotid/ vertebral duplex were 94%, 90%, 94% and 90% respectively.

Catheter angiography in patients with acute ischemic stroke detects an arterial occlusion in 76% patients, when performed within 6 hours of symptom onset [8]. TCD performed by experienced sonographers has been found to match the findings of contrast angiography [2, 9]. TCD has a high sensitivity (>90%) for acute arterial obstructions located in the proximal MCA and ICAs. Up to 90% of patients who receive intravenous TPA within the 3 hours time-window demonstrate an acute occlusion on TCD, especially if the pre-treatment National Institute of Health Stroke Scale (NIHSS) is ≥ 10 points [110, 11]. However, the yield of TCD reduces significantly when performed later than 6 hours after stroke onset [6].

Unlike the smaller coronary arteries that move with each systolic beat, the intracranial arteries are more firmly fixed and can be easily insonated continuously with TCD. Therefore, in patients with an acute arterial occlusion, TCD can be used to monitor the time and patterns of arterial recanalization induced by systemic thrombolysis [11].

TCD has a sensitivity of 91%, and a specificity of 93% compared to angiography for MCA occlusion versus complete recanalization in patients receiving thrombolysis for ischemic stroke [12]. TCD has a moderate sensitivity (55-60%) for posterior circulation lesions [13]. Some of the limitations of TCD can be overcome by using the Power Motion Mode (PMD) TCD, invented by Mark Moehring and Merrill Spencer Figure 1 [14, 15].

Figure 1. Normal transcranial Doppler using the temporal acoustic window with the screen appearance on SONARA TCD system. Upper frame represents the M-mode signatures from right middle cerebral artery, right A1 ACA and left A1 ACA. Lower frame shows the spectra obtained from a depth of 88mm, showing flow pattern in the contralateral A1 ACA.

TCD monitoring during acute stroke thrombolysis is often helpful in therapeutic decision-making for the next most efficient management steps, especially in some cases with persistent occlusion.

A persistent large vessel occlusion or stenosis in patients with acute and spontaneously resolving deficits heralds a greater possibility for the patient's deterioration within the next 24 hours [16]. Furthermore, TCD monitoring during the acute phase can help in guiding the blood pressure levels and head-positioning [17].

PROLONGED TCD MONITORING

No adverse effects have been documented in humans with the currently used ultrasound frequencies in the TCD systems. Prolonged TCD monitoring in acute stroke can help in early prognostication. Slow flow improvement and dampened flow signals are considered as less favorable prognostic signs. On the contrary, early recanalization of an occluded intracranial artery is often associated with rapid and dramatic recovery as well as good long-term outcome in majority of the patients [13]. Labiche et al. [18] showed that most patients who experience early clinical improvement within 2 hours of TPA bolus sustain this clinical benefit 3 months after stroke. On the other hand, Christou et al. [19] noted that among patients who had no change in the severity of neurological deficit or who worsened by 4 or more NIHSS points, none had complete recanalization within 300 minutes, implying that a persisting occlusion on TCD may represent severe ischemia.

Deterioration following improvement (DFI) is considered to be a clinical surrogate marker of intracranial arterial re-occlusion. Arterial re-occlusion following recanalization is believed to be the main underlying mechanism of this phenomenon [20]. Interestingly, patients with early reocclusion had better long-term outcomes than patients with no early recanalization on TCD. Similarly, Rubiera et al. [21] demonstrated a reocclusion rate of 12% in all TPA treated patients and among 17% of those who achieved recanalization. They found that at 3 months, patients with reocclusion and patient with persistent occlusion had significantly worse long-term outcomes than patients with persistent recanalization.

THERAPEUTIC TCD

Unlike the smaller coronary arteries that move with each systolic beat, the intracranial arteries are more firmly fixed and can be easily insonated continuously with TCD. Thrombolysis in Brain Ischemia (TIBI) flow grading system was developed to evaluate residual flow non-invasively and monitor thrombus dissolution in real time [22]. The TIBI system directs our attention to the relatively weak signals with abnormal flow waveforms that can be found along arterial stems filled with thrombi and elaborates on previous definitions of acute arterial occlusion. TIBI flow grades correlate with stroke severity and mortality as well as the likelihood of recanalization and clinical improvement.

Although intravenously-administered tissue plasminogen activator (IV-tPA) remains the only approved therapeutic agent in acute ischemic stroke, the rates of arterial recanalization are considerably low. del Zoppo et al. showed that only 26% of intracranial occlusions lyse

partially or completely after 1 hour of intravenous alteplase infusion [23]. In the PROACT II trial, only 4% of MCA clots showed complete recanalization when recombinant pro-urokinase was infused at the clot surface for 1 hour [24]. Accordingly, half of the patients remain moderately or severely disabled despite treatment with intravenous tPA [25].

Initial in-vitro experiments suggested that low mega-hertz (MHz) to kilo-hertz frequency ultrasound exposure substantially increased the thrombolytic effect of tPA [26-29]. Experiments using cadaver skull showed that 1 hour of 1-MHz TCD helped tPA to recanalize 90% of clots as compared to 30% rate when TCD exposure was limited to 30 minutes [26-28]. A small pressure gradient created by ultrasound waves is believed to provide an opportunity for more tPA molecules to bind with fibrin filaments and stream plasma along the clot, facilitating faster recanalization without harmful mechanical vibrations. Ultrasound enhancement of the thrombolytic effect of tPA does not appear to be mediated by thermal or cavitation effects since the mechanical index remains below 1. Various mechanisms responsible for ultrasound-enhanced thrombolysis include reversible disaggregation of uncross-linked fibrin fibers, microcavity formation in the shallow layers of thrombus, increasing uptake and penetration of tPA into clots as well as residual flow enhancement with microstreaming and vessel dilatation [27-29].

Operator dependency of TCD remains an important hindrance for TCD use as primary imaging modality at most of the centers around the world. Another important limitation, even encountered by experienced sonographers is the insufficient temporal acoustic bone window in 10-30% patients, depending on the ethnicity. Abnormal thickness and porosity of the temporal bone squama is believed to attenuate ultrasound transmission and is seen most commonly among African Americans, Asians and elderly female patients [30].

High rates of complete recanalization and dramatic clinical recovery were initially observed by Alexandrov et al. during tPA infusion and continuous monitoring with 2 MHz TCD [12]. In a small study on 40 stroke patients with mean NIHSS score of 19 points treated with IV- tPA were monitored with continuous 2-MHz TCD showed improved recanalization at 45±20 minutes after tPA bolus [12]. Recanalization was complete in 30% and partial in 40% of the patients while dramatic recovery during TPA infusion occurred in 20% of the patients, who had complete recanalization. Improvement by ≥ 10 NIHSS points or complete recovery was found in 30% of all patients at the end of tPA infusion and in 40% at 24 hours. This preliminary data led to a phase II randomized controlled trial called CLOTBUST, in which 126 acute ischemic stroke patients treated with IV-tPA were randomized to continuous TCD monitoring or placebo (63 patients in each arm) [31]. Complete recanalization or dramatic recovery within 2 hours was noted in 49% in the TCD group as compared to 30% in the control group ($p=0.03$). Only 4.8% patients developed symptomatic intracerebral hemorrhage thus showing a therapeutic benefit with no increased risk.

A multinational prospective observational study based on CLOTBUST trial protocol (CLOTBUST-PRO) is currently evaluating whether early recanalization is independently associated with better 3 month outcome in patients with intracranial arterial occlusions and correlates to a shorter time interval elapsed from symptom onset to IV-tPA bolus [32]. We have recently demonstrated the feasibility and efficacy of ultrasound-assisted thrombolysis in our local Asian patient population [33]. An example of successful recanalization of right mCA is shown in Figure 2.

Eggers et al. [34] evaluated the potential of transcranial color-coded sonography (TCCS)-guided, 2-MHz transcranial ultrasound in enhancing thrombolysis in patients with acute

occlusion of the M1 MCA and with contraindications to the thrombolytic therapy. Recanalization was observed more frequent in the ultrasound group as compared to the control group ($p=0.026$).

Subsequently performed TRUMBI trial [35] included 26 patients within 6 hour of symptom-onset. Patients receiving IV-tPA were randomized to 90 minutes of low-frequency (300kHz) ultrasound exposure or placebo. The study was stopped due to an increased incidence of intracranial hemorrhages (5 of 12 in TPA group versus 13 of 14 in TPA plus ultrasound group). The authors speculated that reverberations of the long wavelength ultrasound occurred inside the head, leading to 'hot-spots' in addition to the mechanical distortion of the microvessels causing parenchymal and even atypical hemorrhages to occur exclusively in the combined treatment group. However, the exact reasons for this observation remain unknown.

Figure 2. Neurovascular findings in a patient with acute right middle cerebral artery (MCA) ischemic stroke. Transcranial Doppler (TCD) performed at tissue plasminogen activator (tPA) bolus injections shows high- resistance TIBI 3 signals in right proximal MCA with flow diversion into the right ACA (A). The patient achieved complete recanalization in the form of normal flow spectra in right MCA (B) at the end of tPA infusion. This was accompanied by significant clinical improvement (NIHSS dropped from 11 to 2 points) during one hour. Brain CT angiography before tPA bolus had confirmed the occlusion of right MCA (C) that recanalized on the imaging performed on day 2 (D).

Ultrasound Contrast Agents and Sonothrombolysis

Although the diagnostic microbubbles or gaseous microspheres were originally developed to improve conventional ultrasound images, a new evolving therapeutic application for this technology is enhancing stroke thrombolysis [36]. When these microbubbles are exposed to an ultrasonic pressure wave, the gas expands, and the spheres oscillate, transmitting mechanical energy momentum to surrounding fluids and accelerating residual flow and possibly eroding at the thrombus [37, 38, 39].

First and second generation microspheres being air-filled, rise up in the container to make the infusion difficult [38, 39]. Their relatively larger size limits their free permeation through pulmonary circulation as well as the thrombus. On the other hand, the 3rd generation lipid coated microspheres are smaller in size and more stable in saline solution. They have a greater transpulmonary passage, producing higher concentrations within the arterial thrombus [38, 39]. In a recent study, it was observed that lipid microspheres permeated beyond the clot in 75% of subjects and improved the residual flow velocity in 83% of subjects [40].

A recently completed pilot trial reported higher recanalization rates with these 3rd generation Perflutren-lipid microspheres with no increase in symptomatic intracranial hemorrhage after systemic thrombolysis [41]. It was also demonstrated that PMD-TCD could quantify the dose of delivered microspheres and determine the minimum amount of microspheres needed to achieve constant flow enhancement and targeted drug delivery [42]. More recently reported TUCSON (transcranial ultrasound in clinical sonothrombolysis) trial evaluated 35 patients with 2 dose-tiers of Perflutren microspheres along with standard IV-tPA and continuous 2-MHz TCD monitoring. The trial concluded that Perflutren lipid microspheres can be safely combined with IV-tPA and ultrasound at a dose of 1.4ml. Although, higher rates intracranial bleeding were observed in the 2nd dose-tier, compared to standard intravenous IV-tPA, a trend toward higher early recanalization and clinical recovery rates therapy were noted [43, 44].

TCD IN CAROTID STENOSIS AND ENDARTERECTOMY

Due to their different acoustic properties compared to the circulating red blood cells, microembolic signals (MES), representing solid or gaseous particles within the blood flow, appear as transient signals of high intensity within the TCD spectrum [45]. They occur at random within the cardiac cycle and they can be acoustically identified by a characteristic ‘chirp’, ‘click’, or ‘whistle’ sound.

Identification of MES is especially important in carotid stenosis to identify patients who may benefit from early carotid endarterectomy (CEA) or more aggressive medical therapy. The CARESS trial revealed that the combination of clopidogrel and aspirin was associated with a marked reduction in MES, compared with aspirin alone [46]. In asymptomatic carotid stenosis, Spence et al. [47] demonstrated that TCD negative cases for MES will not benefit from carotid endarterectomy or stenting unless the operative risk is <1%. They even suggested that asymptomatic carotid stenosis should be managed medically, with delay of surgical intervention until the occurrence of symptoms or emboli.

Selection of patients for carotid revascularization is primarily determined by the presence of neurological symptoms and the severity of carotid stenosis on cervical duplex ultrasonography with confirmation provided by other imaging modalities [48, 49]. TCD can further assist in clinical decision-making by detecting hemodynamic effects of the carotid stenosis [50], identifying the tandem stenotic lesions [51] and determine exhausted vasomotor reactivity and select the high-risk group [52]. Monitoring for MES in patients with symptomatic and asymptomatic carotid stenosis is often used for risk-stratification [53, 54].

TCD is used at some centers for continuous monitoring of ipsilateral MCA flow as well as MES during carotid revascularization procedures. It can help in selecting patients for shunt during CEA and reduce peri-operative complications due to cerebral hypoperfusion [55] as well as for detection of cerebral hyperperfusion syndrome (if MCA velocities increase by more than 1.5 times pre-cross-clamp values and last more than 30 seconds after release of carotid cross-clamps).

TCD IN INTRACRANIAL STENOSIS

Intracranial arterial steno-occlusive lesions cause characteristic Doppler signals such as focal increases in velocity, local turbulence, a post-stenotic drop in velocity and various collateral flow patterns. Up to 10% of TIA and strokes can be attributable to intracranial atherosclerosis [56, 57]. Sensitivity, specificity, positive predictive value and negative predictive values of TCD are generally higher in anterior circulation than the vertebrobasilar circulation, owing to the more reliable anatomy of the former and technical problems in studying the latter [58]. However, PMD TCD has been recently reported with acceptable accuracy parameters, especially when TCD is performed early after the symptom-onset and by experienced sonographers [15]. There is an association between the degree of stenosis and recurrent stroke, with higher degrees of stenosis and the number of vessels affected having a worse prognosis [57, 58].

VASOMOTOR REACTIVITY

Cerebral autoregulation is the ability of brain to regulate its blood supply by compensating for changes in cerebral perfusion pressure. It enables constant cerebral blood flow over a wide range of systemic blood pressure by varying the diameter of the arteriolar sphincters [59]. The steno-occlusive lesions, their hemodynamic consequences and the alternative collateral pathways can be readily detected with digital subtraction cerebral angiography [60], computerized tomographic angiography (CTA) [61], magnetic resonance angiography (MRA) [62] or TCD [63].

Vasomotor reactivity (VMR) is the ability of the cerebral circulation to respond to vasomotor stimuli. This can be evaluated reliably with TCD by monitoring the real-time changes in the flow velocities in response to such stimuli.

The commonest agent to measure VMR is carbon dioxide (CO₂). Increased levels of CO₂ cause vasodilatation and increased cerebral blood flow. Whether the flow velocities represent cerebral blood flow volume (CBFV) remains a debatable issue. Sorteberg [63] stated that the

flow velocity can reflect CBFV and the velocity changes can be proportionate to the changes in CBFV if certain parameters are known and remain constant (e.g., angle of insonation, perfusion territory, arterial diameter) and the effect of only one stimulus is observed.

It is important to note that all these variables remain almost constant over the short period of time during VMR assessment by TCD. Monitoring of MCAs on both sides simultaneously further makes TCD more reliable since the magnitude of vasodilatory challenge as well as all other physiological factors are equal for the affected as well as the healthy MCA, facilitating identification and estimation of the vasodilatory reserve on the side of stenotic lesion.

Measuring VMR requires a proper setup with controlled conditions regarding the concentration of CO₂. Markus et al. [64] described a simple measurement of the MCA velocity in response to 30 seconds of breath holding and termed it as Breath-Holding Index (BHI). BHI is calculated as

$$\text{BHI} = \frac{\text{MFV}_{\text{end}} - \text{MFV}_{\text{baseline}}}{\text{MFV}_{\text{baseline}}} \times \frac{100}{\text{seconds of breath holding}}$$

where MFV is mean flow velocity.

A decreased VMR suggests failure of collateral flow to adapt to the stenosis progression. Therefore, impaired VMR measured by BHI can identify patients at higher risk of stroke who have asymptomatic carotid stenosis or a previously symptomatic carotid occlusion. Various studies, using different provocative measures for assessing the cerebral VMR, demonstrated a remarkable ipsilateral event rate of around 30% (30% risk of stroke/ TIA during about 2 years). In patients with persisting proximal arterial occlusions, hypercapnia can paradoxically decrease the residual flow velocity in the affected vessel at the expected time of normal brain vasodilation when blood pool is shifted to non-ischemic areas. This was described as “reversed Robin Hood” syndrome with the analogy to “rob the poor to feed the rich” in acute ischemic stroke patients [65]. This steal is detectable and measurable by TCD. Bilateral TCD monitoring can identify acute stroke patients with paradoxical velocity responses to hypercapnia or other vasoactive stimuli.

RIGHT-TO-LEFT SHUNT DETECTION

Patent foramen ovale (PFO) is common in general population with a prevalence of 10-35% in various echocardiography and autopsy studies. PFO with right-to-left shunts is considered a potential risk factor for stroke in patients with stroke of unknown etiology [66-74]. Trans-esophageal echocardiography (TEE) is considered as the gold standard for diagnosing PFO. However, TCD with agitated saline-air contrast mixture is a reliable method for detecting the presence of a right-to-left shunt. The sensitivity and specificity of contrast TCD has been reported to be 68-100% and 67-100% respectively [72]. Advantages of TCD

include calibrated valsalva maneuver and the ability to change body positioning during the test [69]. The TCD “bubble” test for right-to-left shunt is superior to transthoracic echocardiography, and possibly TEE. A recent study with TCD and TEE performed simultaneously, showed an almost perfect concordance in PFO detection and right-to-left quantification [70].

USE OF TCD IN SICKLE CELL DISEASE

Children with sickle cell disease have a significantly high risk of stroke before the age of 20 years [75]. Several studies have demonstrated that children aged 2- 16 years with this disease should be monitored with serial TCD evaluations for identifying the patients at an increased risk of stroke [76-77].

The Stroke Prevention in Sickle Cell Disease (STOP) trial [78] evaluated 130 children who had the time-averaged mean of the maximum (TAMM) velocities of > 200 cm/s in one or both of the MCAs or terminal ICAs at baseline TCD.

They were randomized to either blood transfusion or standard care. Over an average follow-up of about 20 months, there was one stroke in the 63 children randomized to transfusion and 11 strokes in the 67 children randomized to standard care, indicating greater than 90% relative risk reduction in stroke incidence in the treated population [79].

TCD FOR VASOSPASM STUDIES IN SUBARACHNOID HEMORRHAGE (SAH)

Diagnosis of vasospasm in patients with subarachnoid hemorrhage (SAH) was one of the first clinical applications of TCD [1, 80]. Vasospasm in SAH is a potentially preventable and reversible condition. Early recognition of vasospasm can be reliably detected with TCD and a timely appropriate therapeutic response can prevent or limit ischemic cerebral damage. The changes in velocity on TCD have been correlated with vessel narrowing measured by angiography, with MCA showing the best degree of correlation [81].

TCD is a useful tool in identifying vasospasm onset, its progression, and its severity as well as for monitoring the effect of therapeutic interventions [82].

TRANSCRANIAL COLOR-CODED DUPLEX (TCCD)

TCCD provides 2-dimensional gray-scale and color Doppler imaging of the circle of Willis. It enables the operator to obtain angle-corrected flow velocities from various intracranial arterial segments [83].

TCCD might be considered more accurate in the assessment of flow velocities than conventional TCD. However, no direct comparisons of both methods in pathologic conditions are available. The flow velocities in the intracranial arteries in healthy individuals are approximately 10% to 30% higher when measured using TCCD as compared to conventional

TCD. The difference is believed to widen in patients with intracranial stenosis. The comparison of the diagnostic efficiency of both methods at the same velocity thresholds cannot be valid and it is difficult to use the flow velocities defined by conventional TCD studies for analyzing intracranial stenosis by TCCD. For instance, WASID study [84] used a mean flow velocity threshold of 100cm/s for MCA. However, these thresholds were observed to be considerably different when TCCD was used. While Kimura et al. [85] found a peak systolic velocity of 180 cm/s as the optimal threshold, Baumgartner et al. [86] suggested peak systolic velocity thresholds of 220 cm/s for the detection of 50% stenosis of the MCA.

Although TCCD has been reported to have high sensitivity and specificity in the detection of a moderate intracranial stenosis [87, 88], it remains operator-dependent and the quality may be adversely affected in patients with insufficient temporal acoustic windows.

FUTURE DEVELOPMENTS

Although, TCD is a simple diagnostic ultrasound method from biophysics stand-point, it is the most complex test in vascular medicine. It offers a wealth of information at bedside about pathogenic mechanism of stroke. Converging lines of evidence suggest that TCD can help in identifying patients at high risk of subsequent cerebral ischemic events. It can be used to monitor the safety and efficacy of various therapeutic interventions rapidly and non-invasively. TCD detection of cerebral microemboli, especially during various therapeutic interventions and cardiovascular surgical procedures, is gradually establishing its role with a potential of being an integral component of the multidisciplinary therapeutic approach in patients with cerebrovascular diseases.

Ultrasound enhanced thrombolysis in acute ischemic stroke, especially with contrast microbubbles, has shown promising results. Advances in TCD continue to improve the capabilities of this technology. Transcranial ultrasound delivery in an operator-independent and dose-controlled manner being tested in a clinical trial, would further strengthen the existing armamentarium of stroke neurologists.

In summary, TCD is an invaluable tool in the diagnostic workup of stroke patients. TCD is also an evolving ultrasound modality with increasing diagnostic value and therapeutic potential. Future technological advances will overcome its limitations by easier bone window location and validated occlusion criteria to ease its use in acute stroke. Widespread availability of TCD would increase the use of this modality in acute stroke. Local validation of diagnostic criteria and test performance is required by vascular laboratory accreditation and quality assurance.

Chapter 6

**INFLAMMATION IN ISCHEMIC STROKE:
MECHANISMS, DIAGNOSIS
AND MANAGEMENT**

***Anna Woodbury, Osama Mohamad, Shan Ping Yu
and Ling Wei****

Department of Anesthesiology,
Emory University School of Medicine, Atlanta, GA, US

ABSTRACT

Inflammation plays an important role in ischemic stroke, not only in the development of atherosclerotic lesions, but also in the processes that lead to apoptosis and further neurological insults following stroke. Interestingly, inflammation also plays an important role in repair and recovery following stroke. This chapter will describe the pathophysiological basis of the inflammatory processes that lead to ischemic injury, the diagnostic imaging modalities (CT, MRI, SPECT, near-infrared fluorescence, etc.) available to predict inflammatory plaque rupture and subsequent thrombosis before it occurs, and the modulation of inflammatory mediators to prevent the spread of stroke and aid in recovery once the insult has developed. The role of the various inflammatory cytokines in cell death and proliferation after ischemia, the integrity of the blood-brain barrier, and the prevention and treatment of stroke will be mentioned. The challenges facing lifestyle modifications as well as prevention of ischemic stroke using current knowledge of the inflammatory processes involved in ischemia will be briefly discussed. Finally, the currently available as well as potential future treatments for ischemic stroke, rehabilitation and general neuroprotection will be discussed. Both conventional and alternative modalities of inflammatory modulation for neuroprotection and neurogenesis following ischemia will be described.

I. INTRODUCTION

With an average of one victim every 40 seconds, almost 795,000 individuals experience a stroke every year. Thus, stroke is the fourth leading cause of death and the number one cause of disability in the adult population in the United States. Although the financial burden for stroke patients and clinical care is enormous, with an estimated cost of >70 billion dollars in 2010, effective stroke therapy has been very limited [1]. Hundreds of drugs that showed significant neuroprotection in animal models (peroxidase inhibitors [2], calcium channel blockers [3], NMDA receptor antagonists [4, 5] and many others) have failed clinical trials in humans [6] indicating that novel and more rigorous design and conduct of animal studies is required to choose the best candidate drugs for human clinical trials. This will increase the chances of successfully transitioning stroke medications. A growing body of scientific evidence from animal models of stroke as well as from human patients shows that inflammation and inflammatory modulators play a larger role in ischemic injury and recovery after stroke than previously credited. Classically, animal studies have shown that antagonizing various inflammatory components could decrease the area of brain infarction, suggesting that inflammation may have primary neurotoxic effects following stroke injury. However, more recent studies have shown that the role of inflammation in stroke is actually more complicated. There is an elaborate interplay involved in inflammatory modulation, resulting in an intricate balance between apoptosis and neuronal regeneration to achieve optimal outcomes following stroke injury. Cells of the neurovascular unit (neurons, astrocytes, pericytes and endothelial cells), microglia, and white blood cells recruited from the systemic circulation, as well as hundreds of cytokines, adhesion molecules and components of the coagulation pathway and the immune system are all involved in a tremendous cascade of events that regulate ischemic injury and contribute to repair and recovery after stroke. As examples of this interplay, this chapter will discuss the dual roles of cytokines, T cells, and microglia in stroke pathogenesis and recovery, including the use of inflammation as a tool in diagnostic imaging of stroke. The chapter will conclude with a discussion of the management options available for ischemic stroke prevention and treatment.

II. PATHOPHYSIOLOGY

Many molecular and cellular components are involved in inflammation as a response to ischemic injury in the brain parenchyma. Among the cells actively involved in inflammation within the brain are brain-specific cells such as microglia, astrocytes, and neurons, as well as circulating immune cells such as T cells and macrophages. Molecular contributors include adhesion molecules, cytokines, and chemokines. These molecules are regulated during the inflammatory process leading to the modulation of ischemic injury and cell death, notably apoptosis and necrosis. The permeability of the blood brain barrier (BBB) following stroke is also an important factor with regards to inflammation and recovery. For example, inflammation is one of several interdependent mechanisms that cause ischemia-induced vascular endothelial cell injury and disruption of the tight junctions of the BBB [7]. In addition, a recent study has suggested that lacunar strokes are associated with diffuse BBB dysfunction in the white matter and are not just ischemic in nature [8]. Cellular adhesion

molecules are important in maintaining the integrity of the BBB and for leukocyte trafficking. Matrix metalloproteases (MMP), a group of proteolytic enzymes heavily involved in tissue remodeling and degradation of extra-cellular proteins, are also involved in the inflammatory response. These proteolytic proteins disrupt the BBB through enzymatic degradation and remodeling of the extracellular matrix [9, 10]. After secretion by various activated cells including leukocytes, MMPs facilitate leukocyte migration and represent one group of enzymes involved in the inflammatory cascade [11].

a. Cytokines

Various cytokines regulate the inflammatory process: interleukin-1 beta (IL-1 β), interleukin-4 (IL-4), interleukin-6 (IL-6), interleukin-8 (IL-8), interleukin-10 (IL-10), interleukin-18 (IL-18) and tumor necrosis factor alpha (TNF- α), among several others. One key regulator of inflammation and cell survival is a downstream signal in the TNF- α pathway, the nuclear factor- κ B (NF- κ B).

NF- κ B is a heterodimeric protein composed of different combinations of members of the Rel family of transcription factors [12]. It is a ubiquitous transcription factor that regulates the expression of pro-inflammatory, pro-apoptotic, and anti-apoptotic genes [13-15]. Thus, NF- κ B acts as a double agent for neuronal survival and apoptosis. Likewise, NF- κ B signaling can have both an apoptotic as well as a neuroprotective effect following cerebral ischemia. For example, activation of NF- κ B in neurons could promote survivability, whereas its activation in glial or immune cells can lead to pathological inflammatory states [16]. Specifically, the p50 subunit is found in the adult brain, and transient middle cerebral artery (MCA) occlusion can induce the nuclear translocation and thus the activation of NF- κ B. Our recent investigation revealed age-dependent neural degenerative changes in p50 knockout (p50^{-/-}) mice. P50^{-/-} mice appeared normal at birth. At 6 and 10 months, the body weight of p50^{-/-} mice was significantly less than that of wild type mice and they started to die from age-related processes. In p50^{-/-} mice, morphological examinations showed: 1) aging and degenerative changes in the cortex and hippocampus including increased lipofuscin granules in neuronal cytoplasm, 2) abnormal capillaries, 3) dark and watery alterations and organelle accumulations, 4) apoptotic glial cells, and 5) DNA damage and caspase-3 positive neurons. These results suggest that p50 plays an important role in neurovascular remodeling, cell survival, and the aging process in the developing CNS [17]. In a consequent investigation in stroke mice, we showed that, after permanent MCA occlusion in p50^{-/-} mice, the ischemic infarct volume and cell death were significantly more severe than that in WT mice. Cell proliferation in regenerative regions such as the subventricular zone (SVZ) was hampered in p50^{-/-} mice. These results suggest that NF- κ B signaling is a neuroprotective mechanism [18]. This is consistent with other reports suggesting that with permanent occlusion of the MCA, decreased NF- κ B activity exacerbates ischemia and leads to increased neuronal death and brain damage [19, 20]. Conversely, some studies have suggested that using p50 null mice or inhibiting NF- κ B subunits in wild-type mice lead to decreased infarct size and increased neuroprotection in some areas of the brain. These data suggest that NF- κ B is a maladaptive factor and a target that should be blocked in transient ischemia [21]. NF- κ B activation may also lead to the proliferation of astrocytes, which regulate neuronal survival and regeneration

during ischemia and the post-injury period. In these ways, NF- κ B plays a dual role in cerebral ischemia, depending on the cell type in which it is expressed, the type and mechanism of ischemic injury (e.g., permanent vs. transient MCA occlusion), and the time point of investigation.

While the downstream mediator NF- κ B seems to be a main contributor to the duality of the inflammatory pathway, other cytokines such as TNF- α , IL-10 and IL-4 are also involved in cell signaling and the modulation of cellular responses involving microglia, T cells, and other inflammatory mediators. In human patients, TNF- α has been shown to be up-regulated in neurons, astrocytes and the invading immune cells at different time points after stroke onset, indicating that TNF- α may be involved in the acute and the delayed processes after ischemic stroke [22]. While it is interesting to see whether neutralizing TNF- α with the monoclonal antibody infliximab would benefit stroke patients, a randomized, double-blinded, placebo-controlled, pilot trial of infliximab did not show any improvement in patients with moderate-to-severe heart failure [23]. In another study to determine the levels of anti-inflammatory cytokines IL-10 and IL-4 in deteriorating ischemic stroke patients, it was shown that early worsening was associated with lower plasma levels of IL-10 in patients with sub-cortical but not cortical infarcts [22]. On the other hand, IL-18, a pro-inflammatory cytokine, increased within the first 24 hours after stroke onset and may be a predictive marker of stroke outcomes [24].

Our evolving understanding of how these cytokines function in the progression of the ischemic insult and how they interact in relation to the complex network of other molecules in the context of stroke is heavily dependent on studies in animal models and the cell types studied. The more knowledge we accumulate about the role of these chemical mediators, the more clinical trials we will be able to administer and the closer to stroke therapy we will be.

b. Microglia

Among the native brain cells involved in inflammation, microglia are highly implicated in mounting an inflammatory response. Microglia are glial cells that are believed to have a low turnover rate. They act as macrophages for the central nervous system, engulf infectious agents that penetrate the BBB and present antigens for T-cell activation. Resident microglia are believed to be bone-marrow/mesenchymal monocytes that reach the brain during development and differentiate into a resting or surveying phenotype within the parenchyma. In pathological conditions, microglia can proliferate substantially, become activated, and change their profile, becoming amoeboid in appearance with multiple branches and extensions [25]. IFN- γ can activate microglia which initiate a positive feedback loop, activating more microglia and creating a cytokine activation cascade including the release of TNF- α . Microglia also produce chemotactic molecules that can recruit T-cells to the site of injury [26].

Microglia are capable of producing large amounts of hydrogen peroxide and nitric oxide that can destroy both healthy and unhealthy cells. They also produce proteases, cytokines, glutamate, and aspartate, which can lead to direct cellular damage, axonal demyelination, and neuronal cytotoxicity. While their cytotoxic secretions are intended to destroy infected neurons and invading pathologic agents, the process may result in large amounts of reactive oxygen species that damage healthy neuronal bystanders. Thus, various anti-inflammatory

drugs such as indomethacin [27] and minocycline [28] have been used to target microglial activation and inflammation following acute stroke.

However, following the inflammatory response, microglia can serve to promote neural growth and rewiring through synaptic stripping, secretion of cytokines, and recruitment of neuronal progenitors to the infarct [29]. Thus, microglia exert both a supportive as well as an inhibitory role in inflammation and neural protection in the context of stroke. Increasing evidence implicates that microglia may have a supportive role and lead to beneficial steps in adult neurogenesis [25-31]. The effect of microglia on adult neurogenesis depends upon the subpopulation of microglia present in the brain, their state of activation and their functional phenotype. This activation state and phenotype is typically dependent on the chronicity of the injury. Following acute injury, neurogenesis occurs in the SVZ and the subgranular zone (SGZ) of the hippocampus. However, about 80% of these stroke-generated striatal neurons die in the first 2 weeks after they are formed [32]. Inflammation and microglial activation were initially blamed for the cytotoxic milieu that lead to the death of these newly formed neurons. However, neurogenesis can continue for over 1 year following stroke [33] and recent evidence has shown that the early cytotoxic, detrimental effects of microglia following stroke can later be transformed into a supportive state during the chronic, recovery phase. Microglia in these situations can support different steps in the process of neurogenesis; the survival, proliferation, and migration of neuroblasts and their differentiation to mature neurons [34]. This chronic, recovery phase must be distinguished from neuroinflammation, in which chronic microglial activation could lead to accumulated destruction in long-term pathological states such as that of Alzheimer's disease [35].

When activated microglia change into a chronic profile, their phenotype can either remain the same or change to another activation state, which can be either maladaptive or, potentially, neuroprotective. For example, microglia chronically exposed to LPS *in vitro* reduce the production of pro-inflammatory cytokines TNF- α , IL-1 α , IL-1 β , and IL-6 and free radicals such as nitric oxide, while retaining or enhancing suppressors of the pro-inflammatory function of microglia such as PGE₂ and IL-10 [31]. Secretion of PGE₂ inhibits microglial pro-inflammatory responses and down-regulates T-helper cells [36]. Despite chronic microglial activation, newly formed neurons that survive beyond the first month following deleterious microglial activation will continue to survive for at least 6 months following the insult [37]. Further, neuroblasts were rescued by microglia and microglia-conditioned medium *in vitro*, compared to neuroblast formation from SVC neural stem cells that were not cultured in conditioned media or co-cultured with microglia [38, 39].

Given the significant contribution of microglia to post-stroke injury and recovery, several imaging techniques have been developed to explore the dynamics of microglial transformation from the resting to the active states [40]. In summary, there is a delicate balance between the pro-inflammatory and anti-inflammatory effects of microglia on survival and neurogenesis, and much of this distinction results from the activation state and phenotype of microglial subtypes in the acute and chronic states following an initial injury to the brain. Microglia preserve homeostasis in the brain through secretion of extracellular signaling molecules and interaction with other cells. Thus, different activation states and phenotypes can result in microglial secretion of supportive as well as detrimental factors.

c. T Cells

Like microglia, different subsets of T lymphocytes play different roles in the modulation of the inflammatory response. Similarly, the activity of these T cells is up-regulated or down-regulated depending on the acuity of the injury. This activity can either be harmful to regenerating neurons through the acute release of pro-inflammatory cytokines and cytotoxins, or, later in the recovery phase, beneficial.

Initially following stroke, T cells enter the damaged region and contribute to tissue injury through non-specific mechanisms [41]. Studies have shown that suppressing this T cell entry can improve outcomes in experimentally induced stroke [42, 43]. Lymphocyte deficient mice have had consistently smaller infarct volumes and better functional recovery compared to wild-type controls in multiple studies involving ischemia and reperfusion [44-46]. Furthermore, mice lacking RANTES (CCL5), a chemokine attractant for T cells, have smaller infarct volumes following reperfusion as well [47]. However, this protection in T-cell deficient mice is lost when permanent ischemia without reperfusion is induced [48]. CD73, an ecto-5' nucleotidase expressed on a variety of cells including leukocytes, has been shown to rescue CD73 (-/-) mice from ischemic brain injury, and to decrease infarct volume and local accumulation of leukocyte subsets [49]. These studies about the damaging effects of acute inflammation have led to the development of various experimental therapies aiming at preventing T-cell infiltration into the brain and T cell activation following stroke, such as FTY720, FK506, Cyclosporin A, RTL551, and chemokine receptor antagonists [42, 50, 51].

However, the different subpopulations of T cells must be taken into consideration when approaching the treatment of stroke through T cell suppression. T lymphocytes are leukocytes derived from the bone marrow, then mature in the thymus and are essential in the immune system for clearing pathogens. T cells are subtyped based on their expression of co-receptor proteins (CD3, CD4, or CD8) and the types of cytokines they secrete. In this way, they can promote cell-mediated, inflammatory, humoral, and allergic responses. In the context of stroke injury, CD8⁺ cytotoxic T cells may contribute to post-stroke brain injury by extending the area of damage, while CD4⁺ regulatory T cells (Tregs) may limit these damaging effects. Natural killer T cells are necessary to prevent infections that might occur post-stroke [52]. Additionally, CD4⁺ helper T cells, especially Tregs, may contribute to repair processes and brain recovery in the subsequent days following stroke onset. Tregs limit the immune responses by releasing transforming growth factor beta (TGF- β) and IL-10, and in this way prevent the onset of autoimmune disorders [53, 54]. Tregs suppress inflammation and have also been reported to be neuroprotective, potentially by modulating harmful actions from microglia [55]. These cells may also function in stroke recovery through direct production of growth factors such as ciliary derived neurotrophic factor (CDNF) and TGF- β [56]. When T cells are depleted, neurogenesis is impaired implying that the nuclear factor of activated T cells (NFAT) is required for neuronal survival [57-59]. This action is primarily mediated through CD4⁺ CNS-specific T cells and Treg cells, partially through BDNF secretion, and appears to be lost in permanent ischemia models [60, 61]. Timing of post stroke T-cell targeted therapy is therefore an important consideration, so that the beneficial effects of T cell-mediated neuronal regeneration and anti-inflammatory actions are not unintentionally blocked.

On the first day following a stroke, the number of circulating T cells may be reduced, while on post-stroke days 7 and 21, the number of CD4⁺CD25⁺ T cells and Tregs is

increased [62]. In a subsequent study by Yan et al., there was an overall increase in Tregs in the peripheral blood following stroke for up to 3 weeks. Interestingly, the increase in Tregs occurred only in male stroke patients, and the decreased number of Tregs in females seemed to have an impaired ability to suppress T cell proliferation [63]. This may suggest an important role for Tregs in modulating the extent of stroke injury, especially that it has been noted that female ischemic stroke patients often have worse outcomes than males [64, 65]. Investigations into the use of Tregs to induce protection following stroke are still ongoing.

T lymphocytes may also have an important role in stroke-induced immunodeficiency syndrome. As early as 12 hours following ischemic stroke, a systemic immune depression can begin and last for several weeks. This suppression of the immune system which is mediated by hyperactivity of the sympathetic nervous system and the hypothalamic-pituitary-adrenal axis, potentially through activation of the $\alpha 7$ nicotinic acetylcholine receptor ($\alpha 7$ nAChR) pathway, results in reduced numbers of T cells, atrophy of lymphatic organs, and infectious complications of the urinary and respiratory tracts within the first few days after stroke [66-70]. One treatment that has been used to suppress this response is propranolol [71]. Another mediator of stroke-induced immune depression is the vagal “cholinergic anti-inflammatory pathway”, in which the release of acetylcholine after vagal activation by pro-inflammatory cytokines results in the inhibition of further pro-inflammatory mediator release [72, 73]. Thus, in creating novel therapies to regulate T cell migration and activation, caution must be maintained to prevent further depressing an already weakened immune system.

Intercellular adhesion molecule 1 (ICAM-1 or CD54) is expressed on the surface of endothelial cells and leukocytes and aids in leukocyte adhesion and transmigration to brain parenchyma after stroke. Several studies have shown that ICAM-1 inhibition reduces neurological damage in animal models of stroke [74, 75]. Enlimomab, a monoclonal antibody against ICAM-1, has been tested in a clinical trial for stroke patients [76]. 625 patients were enrolled and Enlimomab was administered to 317 patients within 6 hours of stroke onset. Enlimomab was not found to be effective in the treatment of stroke and was even associated with more adverse effects primarily infections and fever. It was postulated that antibody production against Enlimomab together with a wide-spread immune system activation in stroke patients were responsible for the worsening of symptoms in the experimental arm [77]. In another test of anti-leukocyte adhesion strategy, a humanized anti-E/P-selectin antibody was found to be safe and effective in non-human primate stroke animals [78]. This antibody has not been used as a clinical treatment for human stroke patients yet.

III. DIAGNOSTIC IMAGING

Carotid atherosclerotic plaque rupture and thrombus formation are commonly known pathophysiological phenomena involved in the development of ischemic stroke. For this reason, recent attention has turned towards using diagnostic imaging to predict plaque rupture before it occurs. Plaques that are likely to rupture tend to have large, eccentric, necrotic cores and thin fibrous caps. Spotty calcifications and proliferation of the vasa vasorum, with heavy infiltration of inflammatory cells especially macrophages are typical characteristics of a mature plaque. Rupture mainly occurs in the shoulder where apoptotic cells and macrophages release proteolytic enzymes such as MMPs. Some imaging modalities have targeted the

identification of these metalloproteases for their predictive value. The identification of molecular surrogates to detect plaque rupture without diagnostic imaging is currently an ongoing area of research, but until these surrogates are found, noninvasive imaging modalities combined with clinical symptoms remain the mainstay for stroke prediction and treatment guidance [79].

a. Computed Tomography (CT)

CT has long been used to diagnose acute stroke when it occurs, particularly given the accessibility of CT to clinicians and its ability to rapidly image unstable patients in an emergency setting. Because of the availability and widespread use of CT for diagnosing stroke patients, studies have been performed to analyze the ability of CT as a predictive tool. For recurrent strokes following a minor stroke or transient ischemic attack, CT/CTA (CT-angiography) was not significantly different from MRI in its ability to predict stroke recurrence, indicating that CT/CTA could be an effective substitute for MRI at institutions where it is the imaging modality that is more readily available [80]. Recently, CT has been used in an attempt to predict plaque ulceration and rupture in at risk patients as well. In a series of 346 patients experiencing anterior circulation symptoms, multi-detector CT angiography (MD-CTA) was used to evaluate plaque presence, degree of stenosis, and ulceration in the carotid artery [81]. Measurements included plaque volume and composition: lipid rich necrotic core, fibrous tissue, and calcification. Plaque was identified in 185 of these symptomatic patients, with ulcerations in 38 of them, independent of the degree of stenosis. These results may help clinicians to identify rupture-prone plaques and improve risk stratification based on analysis of plaque composition and measurement of plaque volume, rather than simply based on a moderate-to-high degree of stenosis.

b. Magnetic Resonance Imaging (MRI)

MRI has proven to be a useful diagnostic tool in distinguishing plaque components using non-invasive imaging. MRI can differentiate fibrous cap, necrotic cores, intraplaque hemorrhage and calcification, and thus can correlate with clinical symptomatology [82]. Studies on local hemodynamic forces and shear stresses near the area of carotid arteriosclerosis have been performed to allow for noninvasive dynamic assessment of developing atherosclerotic plaques [83].

Other studies have focused on the development of targeted molecular contrast agents such as P947, an MMP inhibitor that has been coupled to gadolinium chelate [84]. MMP expression has resulted in higher signal intensities in the shoulder regions and fibrous cap in MRI, as expected [85].

Disadvantages include poor reproducibility and difficulty in imaging small arteries, as well as unknown probe toxicity. However, high-resolution MRI as an imaging tool with sub-millimeter spatial resolution and lack of harmful radiation could prove to be a very useful tool for detecting MMP activity, evaluating atherosclerosis, and potentially predicting the likelihood of plaque rupture and guiding treatment [86].

Alternatively, USPIO-MRI (using ultra-small super-paramagnetic iron oxide –USPIO- as a cell specific contrast agent) has been successfully applied for the *in vivo* imaging of macrophages as markers of inflammation in stroke patients. USPIO-MRI allowed the imaging of macrophage infiltration into the ischemic brain [87, 88] and the identification of inflamed carotid plaque lesions in stroke-prone patients [89].

c. Ultrasound

Ultrasound modalities may be invasive or non-invasive. Intravascular, invasive ultrasound produces high-resolution images that have been found useful in distinguishing the morphological characteristics of carotid plaques and predicting stroke occurrence. The safety of intravascular ultrasound with and without an embolic-protection device was evaluated in a series of patients with >50% internal carotid artery stenosis and found to be safe [90]. However, invasive methods of ultrasound are not always necessary.

Plaque mobility is a salient feature in non-invasive ultrasound imaging for predicting the likelihood of plaque rupture. Progressive ischemic symptoms are more frequently associated with mobile plaques, and histology shows that mobile plaques tend to have a higher incidence of mural thrombus and a higher ratio of necrotic core to plaque area [91]. The mobility of the plaque has been described as the “jellyfish sign” on B-mode ultrasound, because the plaque surface moves in a manner that is discordant with the arterial pulse. The jellyfish sign suggests potential rupture of the fibrous cap and thrombogenic factor release into the arterial lumen. It is associated with a repeated stroke shortly following diagnosis and has been found to be more predictive of high-risk plaque vulnerability than intra-plaque hemorrhage [92].

d. Single Photon Emission Computed Tomography (SPECT)

Use of SPECT for monitoring patients at risk of atherosclerosis is primarily limited by the amount of radiation delivered with radiotracers necessary for imaging. However, it does have the benefit of being non-invasive, sensitive, already in clinical use, and more available than PET. Most studies to date involving the identification of high-risk plaques have been performed in animals, using MMPs as a high-risk marker of plaque vulnerability, given its role in the destabilization of atherosclerotic plaques. The first studies involving SPECT to identify inflammatory components in atherosclerotic plaques used New Zealand white rabbits with balloon-induced endothelial injury followed by a high-fat and cholesterol diet [93, 94]. MMP inhibitor uptake was easily visualized by microSPECT, following intravenous administration of the tracer. The results were confirmed with immunohistochemistry, and the uptake of the MMP inhibitor was decreased following diet modification and statin therapy. Subsequent studies showed similar results with different MMP inhibitors, radio-probes, and radiotracers [95]. DTPA-SPECT has been used in the period after acute stroke to evaluate the integrity of the BBB and its correlation with post-stroke seizures and worsened post-stroke outcomes as well [95, 96].

e. Near-Infrared Fluorescence (NIRF)

NIRF has the benefit of being a non-invasive, non-irradiating form of diagnostic imaging. It operates in the near-infrared spectrum, creating fluorescent images that can detect MMP activity. Because of the way in which the protease cleaves the fluorochromes, and the depth of penetration, there is an amplification of fluorescence and a relative improvement in the image as compared to SPECT for *in vivo* imaging [97]. NIRF has been used to examine MMP activity following cerebral ischemia as well [98]. Not only has NIRF been used to identify MMP activity, it has also been used to examine fibrin deposition and progression to thrombo-embolic stroke in mice, using activated Factor XIII (FXIIIa) as a target [99]. Despite these promising results, limitations of NIRF include low sensitivity and limited spatial resolution, unknown dye toxicity profiles, and studies have been performed only in animals and *ex vivo* human artery plaques [86].

NIRF was first applied to human carotid artery plaques in 2009 [100]. This study allowed for the detection of differential topographic NIRF signals in an excised plaque, with low-intensity cold spots and high intensity hot spots. However, anatomical topography and NIRF probe detection do not completely correlate, indicating that NIRF may be detecting more molecular susceptibility that is not always identifiable with conventional imaging. This ability to potentially identify more vulnerable plaques could therefore improve selection criteria for surgical interventions, if applied to human patients *in vivo*.

IV. PREVENTION AND TREATMENT

a. Prevention

Although there are some who disagree, conventional wisdom and current guidelines suggest that eating a diet high in fresh fruits, vegetables, and low-fat dairy products, combined with a high intake of dietary and soluble fibers, whole grains and protein from plant sources and decreasing consumption of saturated fat, cholesterol and sodium, can aid in the prevention of stroke [101]. Other lifestyle modifications that have shown strong evidence for stroke prevention include participation in moderate exercise (30 to 60 minutes) 4 to 7 days per week. Maintaining a low-normal body mass index, smoking cessation, and decreasing alcohol consumption are also important factors in reducing stroke and cardiovascular risks, particularly since smokers are at almost 4 times increased risk for stroke relative to nonsmokers.

Guidelines for secondary stroke prevention include intravenous tissue-type plasminogen activator (tPA), anti-hypertensives, anti-thrombotics, anticoagulants for atrial fibrillation, lipid-lowering medications, smoking cessation, and weight loss education. There are, however, unfortunate regional variations in care, with many individuals still receiving suboptimal stroke therapy [102]. Management of hypertension, cholesterol, diabetes, and atrial fibrillation should be priorities for stroke prevention. In terms of blood pressure management, diastolic blood pressure should be maintained at <90 mmHg, and systolic blood pressure should be <140 mmHg. Blood pressure targets should be lower in those with a history of stroke or diabetes. Lipid management with statins should be initiated in those at

risk of stroke, since a 20 to 30 percent relative risk reduction in recurrent vascular events has been reported for patients without coronary artery disease and who have a history of stroke after lipid management with statins [101].

b. Treatment

b1. Currently Available Therapies

Stroke is one of the leading causes of morbidity and mortality worldwide [1] and yet there is a paucity of acceptable treatments that improve neurological recovery. The current guidelines include emergent management and supportive care for stroke patients, along with early thrombolysis, volume expansion for hemodilution, pressure support or anti-hypertensives as indicated [103]. Mechanical Embolus Removal in Cerebral Ischemia (MERCI) devices for extraction of intra-arterial thrombi may also be used in selected patients within 6 hours of MCA occlusion, but further trials on intra-arterial thrombolysis therapies are needed, despite current recommendations from the European and American Stroke Associations. Recommendations from the American Stroke Association (ASA) further include initiating anti-platelet therapy with aspirin within 24-48 hours of ischemic stroke, assessment of swallowing with appropriate nutritional support if needed, early ambulation and deep venous thrombosis prophylaxis, and treatment of recurrent post-stroke seizures as well as initiation of antibiotic therapy for suspected infections. Additional treatment of acute neurological complications include measures such as mannitol to lessen the risk of edema, hyperventilation to decrease intracranial pressure, ventricular drain placement for acute hydrocephalus, and decompressive surgical evacuation of a space-occupying cerebellar infarction [103].

Aside from supportive care, currently available treatment modalities for acute ischemic stroke primarily target tissue reperfusion through thrombolytics such as tPA in the immediate period following injury. The use of tPA is, however, limited by time, having a small window of administration of approximately 3 - 4.5 hours following stroke, and carries with it the risk of hemorrhage, since it works by clot dissolution. Newer generation thrombolytic agents have shorter durations of action and are more fibrin-specific, but of the recombinant tPAs available, only alteplase has been FDA approved [103].

After injury has occurred, the most promising method of neurological recovery remains prevention of further stroke or stroke-related complications (vasospasm, infection, hemorrhage, reperfusion injury) and rehabilitation. Peripheral stimulation and physical therapy can improve functional recovery and neurovascular plasticity in the central nervous system. This has been confirmed by animal studies using peripheral stimulation following focal ischemia in mice. Peripheral stimulation resulted in increased angiogenic factors such as VEGF, restoration of local cerebral blood flow, enhanced neuroblast migration through up-regulation of chemokines such as those in the SDF-1/CXCR4 signaling pathway, and enhanced neurogenesis [104].

Another available therapy to limit brain injury and promote neurological recovery following stroke involves mild to moderate hypothermia (reducing body/brain temperature by 3-5°C). Both animal and human data show that hypothermia is protective against various brain insults [105-109]. Clinical evidence shows that a 3 to 5°C reduction is generally safe

and effective in reducing cell death and improving outcomes after brain ischemia [110]. Moderate hypothermia reduces intracranial pressure, increases cerebral perfusion pressure [111], and reduces the risk of brain edema and hemorrhage [112]. In the clinic, hypothermia is the only neuroprotective therapeutic treatment for cerebral ischemia that has successfully managed the transfer from bench to bedside, and it is an approved therapy for patients after cardiac arrest and children with hypoxic-ischemic encephalopathy [113].

Hypothermia protects the brain in multiple ways [114]. It reduces cerebral demand on neuronal activity and prevents excitotoxicity [109]. In addition, it suppresses the production of oxygen free radicals and inhibits pathways related to BBB degeneration [114]. Hypothermia-induced neuroprotection is also associated with blocking many of the processes leading to apoptosis [115] and suppressing the inflammatory response observed in brain ischemia [116-118]. Lending further support for the beneficial effects of hypothermia therapy, there is a general consensus that pyrexia and temperatures $>37^{\circ}\text{C}$ following ischemia are associated with poor patient outcomes [119]. Higher body temperature (hyperthermia) of approximately $37\text{--}40^{\circ}\text{C}$ after circulatory arrest is a common clinical symptom and it worsens outcomes [119]. There is consistent evidence that early (noninfectious) hyperthermia after stroke is associated with a marked increase in morbidity, mortality, and size of the brain infarct [119]. After a severe MCA thrombotic infarct, brain temperature exceeds body core temperature by up to 1.5°C [109] and pyrexia is independently and significantly associated with indices of stroke severity and 90 day mortality [120]. Post-stroke pyrexia is associated with significantly higher morbidity and mortality rates (43% increased risk of fatal outcome) as compared with afebrile patients [121]. In a large hospital-based observational study of patients with acute ischemic stroke, body temperature above 37.5°C was associated with poorer outcome compared to normothermic patients [122]. Supporting the importance of controlling post-stroke temperature, decreasing body temperature from 36.8 to 35.5°C resulted in $\sim 50\%$ risk reduction in fatality [123].

On the other hand, it is generally agreed that severe hypothermia, i.e., reducing body temperature below 30°C , may cause adverse effects such as increased risk of hemorrhage, cardiac, pulmonary or renal damage, electrolyte imbalance, and infections. Hypothermia can cause decreases in systemic blood pressure, especially during the cooling phase [124]. There are only few circumstances where intensive cooling can be applied in clinical settings. For example, in major vascular and neurological surgeries, the target of cooling is sometimes EEG silencing, an indication that cerebral metabolism has slowed to near-non-existence [125]. However, such extensive cooling would be impractical for awake patients, and is only applicable primarily to the anesthetized patient undergoing surgery. In general, for every 1°C decrease in temperature, there is a proportional 6% drop in cerebral metabolic rate [126]. Cooling also leads to a decrease in inflammatory mediator release by altering IL-6 and IL- 1α resulting in decreased cell death and apoptosis in animal models [116]. Cooling can be induced via endovascular as well as external modalities, such as indwelling catheters and cooling blankets. Immediate initiation of hypothermia should, theoretically, protect injured tissues and cells from further damage resulting from inflammation, edema, excitotoxicity, and increased metabolic turnover. Rewarming must then be performed much more slowly, as rapid rewarming can lead to an increase in brain edema and cerebrovascular volume due to the rapid increase in cerebral blood flow that comes with decreased cerebrovascular resistance [127].

One recent meta-analysis showed that mild hypothermia to 33°C does not significantly affect stroke severity and has no impact on mortality [128]. However, therapeutic hypothermia continues to be studied in an attempt to elucidate the ideal degree of cooling and the settings in which it can be used, with the promise of randomized controlled trials underway [128, 129]. Those studies that do show a benefit of cooling for ischemic stroke indicate that cooling must be initiated immediately following ischemia, so that target temperatures are reached in the tissues of interest rapidly following injury. Another study of the acute effects of localized cortical hypothermia on dendritic structural damage following ischemia showed that neither moderate hypothermia to 31°C nor deep hypothermia to 22°C blocked the onset of dendritic blebbing or dendritic spine loss in mice. However, during reperfusion, hypothermia did more consistently promote recovery of dendritic structure and spines [130].

Mild hypothermia to 34°C has been shown to decrease infarct volume and reduce brain swelling in experimental stroke when combined with thrombolysis [131]. In the same study, rats exposed to mild hypothermia and tPA had improved neurological scores relative to rats exposed to tPA alone, indicating that hypothermia can reduce the tPA-related side effects of reperfusion. Even though hypothermia could be potentially beneficial and neuroprotective in ischemic stroke, physical cooling is limited by time and increased whole body energy consumption. Other side effects of severe hypothermia include hypoglycemia and alkalosis [132, 133]. Not only does surface cooling require 3-6 hours to achieve a 2-5°C temperature reduction, but shivering and sympathetic activation are both homeostatic mechanisms that could increase metabolism and oxygen consumption, potentially contributing to worsening ischemia. Therefore, physical hypothermia is often limited to sedated or non-responsive patients in an attempt to prevent shivering.

b2. Novel Therapies

Since the available treatments for stroke are primarily preventive and supportive, and those that are meant for the acute treatment of stroke (tPA and cooling) come with undesirable side effects, ongoing research is developing new modalities of neurological preservation, recovery, and regeneration.

Pharmacologically Induced Hypothermia

Because of the complications associated with physical cooling, research has developed drugs to induce hypothermia pharmacologically. Paracetamol can induce hypothermia resulting in only a ~ 1°C decrease in core temperature and, thus, is insufficient for neuroprotection.

Newer pharmacological agents being used in experimental trials are meant to decrease the “set-point” in the brain’s thermoregulatory center, to more safely produce clinically significant hypothermia without altering other physiologic parameters.

Targets for pharmacologically induced hypothermia include transient receptor potential vanilloid-1 (TRPV1) agonists and neurotensin receptor 1 (NTR1) agonists [134-136]. TRPV1 receptor agonist rinvanil at 25 mg/kg induces hypothermia to about 33.4°C 30 minutes after injection in animals, returning to normal temperatures about 2.2 hours later. Higher doses resulted in a similar degree of hypothermia, but for longer time periods. Rinvanil could be given intracerebroventricularly and it reduces both O₂ consumption and skin temperature [137].

In an effort to overcome the limitations by forced physical cooling, we have generated novel neurotensin compounds that are centrally acting on the "thermoreceptor" neurotensin receptor 1 (NTR1) and could effectively induce "regulated hypothermia" only minutes after administration without triggering shivering. Post-ischemic administration of these compounds attenuates ischemia-induced brain injury and promotes functional recovery in experimental stroke models of rodents [138]. These compounds thus provide a novel means of hypothermia therapy and further investigations on the safety and effectiveness of these hypothermic drugs may help to translate this pharmacologically induced hypothermia therapy to human patients.

Erythropoietin

A crucial component to ischemic stroke therapy is restoration of blood supply. Thrombolytics can be used immediately in an attempt to dissolve clots and reduce ischemic time, but these agents carry with them the risk of hemorrhage, resulting in potentially worsened neurological damage and increased infarct size. However, newer agents such as Erythropoietin are currently being studied in an attempt to restore local blood supply and achieve neuroprotection without paradoxical reperfusion injury.

Erythropoietin is a hematopoietic cytokine that stimulates erythropoiesis and has been observed to have neuroprotective qualities in the central nervous system [139, 140]. It is expressed on different cells within the central nervous system: neurons, astrocytes, and endothelial cells [141]. Erythropoietin has an anti-apoptotic effect on neurons and other cell types, including cerebral vascular cells, and its neuroprotective effect is dependent on protein kinase B activation and mitochondrial maintenance, as well as regulation of caspase activation [142-145]. Erythropoietin has also been shown to have anti-inflammatory properties, including blocking a secondary rise in IL-1 β and other inflammatory mediators [146]. When administered 30 minutes prior to ischemia and once per day after an ischemic event in animal studies, recombinant human Erythropoietin treatment was found to attenuate ischemia-induced cell death, decrease infarct size, enhance post-ischemia angiogenesis, and restore local cerebral blood flow to the post-ischemic cortex [147]. Erythropoietin has also been shown to reduce endothelial cell death in the ischemic penumbra in neonatal rats [148].

In clinical trials, treatment with *Darbepoetin alfa* for prophylactic neuroprotection prior to aortic surgery seemed to have some benefit [149], but this study was halted prematurely when a multi-center German study showed possible harm from using Erythropoietin in the treatment of acute ischemic stroke [150].

Due to concerns regarding thrombo-embolic complications from Erythropoietin, most of the German Multicenter EPO Stroke Trial patients received systemic thrombolysis with tPA, when eligible. Unfortunately, patients who were administered tPA and Erythropoietin had a higher overall mortality than those administered tPA alone, suggesting that there may be yet unknown harmful interactions involved with administering Erythropoietin in combination with tPA for the treatment of acute ischemic stroke. However, in a previous study by the same group, there was an overall benefit with decreased infarct size and improved functional outcome when high-dose intravenous Erythropoietin was administered to a small group of patients <80 years old, as compared to placebo [151]. One recent study involved the use of pegylated liposomes for the targeted drug delivery of Erythropoietin to damaged areas of the brain to decrease cerebral ischemia/reperfusion injury [152]. Another group used hydrogel for direct, concentrated delivery of Erythropoietin to stimulate neurological recovery following stroke in animal models [153]. These new, targeted delivery methods may result in improved

avoidance of side effects and safer method of Erythropoietin administration, but this has yet to be confirmed in human studies.

Other Neuroprotective Agents

Agents such as valproate, DL-3-n-Butylphthalide and the neural peptide apelin have been shown to be neuroprotective in various studies, and may eventually have clinical benefit when applied to stroke management. Valproate is an anti-convulsant that has been shown to be neuroprotective following transient global ischemia in rats [154]. It significantly increased the density of neurons in the hippocampal CA1 region one week after the ischemic event, and suppressed microglial activation and number of microglia, indicating a role for valproate in inhibiting the cerebral inflammatory cascade as well. Apelin, an endogenous neural peptide, has been shown to be neuroprotective in cortical cultures, reducing markers of neuronal apoptosis [155]. DL-3-n-Butylphthalide is a cytoprotective compound synthesized from the seeds of *Apium graveolens* Linn (Apiaceae), commonly known as celery, and it has been shown to prevent neuronal death after focal cerebral ischemia in mice through the JNK pathway [156].

Other putative neuroprotective agents include thrombin, honokiol, curcumin and their derivatives [157-159]. Whether these compounds are effective in clinical trials for neuroprotection and recovery following ischemic stroke is yet to be determined. Electroacupuncture could also provide a promising field of research for stroke rehabilitation and neuroprotection as well, and has been shown to attenuate cerebral ischemic injury through an anti-inflammatory action in animal models [160]. These results need to be more consistently reproduced before the use of such therapies gains wide acceptance in the medical community.

Cell-Based Therapies

Successive failures in translating stroke drugs to the bedside prompted scientists to look for therapy in stem cells. Stem cell transplantation is a promising therapy for ischemic stroke to replace lost tissue and provide trophic support that limits inflammation and enhances endogenous repair mechanisms [161]. Regeneration of the brain after ischemia requires an active replacement of blood vessels, neurons and glial cells and the integration of the endogenously regenerated or transplanted cells in functional networks. Studies from our lab and others have shown that transplanted stem cells survive, differentiate, enhance functional recovery [162-164] and suppress inflammation [165, 166] after ischemia. Stem cells differentiate to neurons, glial and endothelial cells and provide trophic support that enhances endogenous repair mechanisms (angiogenesis and neurogenesis) [167]. Many types of stem cells have been used as therapy for stroke: embryonic [168], bone marrow [169, 170] and cord blood [171] cells. Studies have also shown that transplantation of human embryonic stem cells improves functional recovery after ischemic stroke [172, 173]. Recently, scientists, using a cocktail of transcription factors, reprogrammed mouse [174] and human [175] fibroblasts to pluripotent stem cells which are able to differentiate to all the three germ layers. Moreover, fibroblasts have been directly converted to neurons and neural progenitors [176-178]. The potential of these induced cells in the treatment of ischemic stroke is being investigated in animal models of stroke. There are tens of clinical trials that are currently testing the potential of hematopoietic bone marrow mesenchymal or adult neural stem cells for the treatment of ischemic stroke. A full list of these trials can be found on

clinicaltrials.gov. Most studies are either recruiting or in progress and no large randomized trials have been performed [179]. Geron, a biotechnology company and the first to start a clinical trial for human embryonic stem cells in spinal cord injury patients, has halted its trial due to money scarcity. Whether stem cells will be effective in the treatment of human stroke patients is yet to be determined.

SUMMARY AND CONCLUSION

Cytokines, microglia and cells of the immune system interact in a yet to be disclosed fashion to produce a complicated inflammatory cascade of events that contribute to tissue injury and regeneration. More studies are required to fully understand how these cells and molecules interact before therapies are to be developed. Current guidelines recommend quick diagnosis and treatment of ischemic stroke with CT/MRI guided imaging, supportive therapy, and immediate thrombolytic treatment. This is followed by prevention of stroke recurrence through dietary and lifestyle modifications, as well as anti-platelet therapy and management of co-morbidities. There are currently no agents approved for usage to increase neuronal regeneration, but research is underway. Many of these novel agents target inflammation and apoptosis in an effort to decrease neuronal destruction and infarct volume following ischemia-reperfusion injury. The complete inhibition of apoptosis and the inflammatory cascade would clearly be maladaptive for a number of reasons, as both are necessary processes to promote accurate neuronal mapping and to protect the host from infections and other onslaughts. However, the overwhelming surge of cytokines and cellular death that immediately follows brain injury can be detrimental as well. As with all things, a harmonious balance must be struck so that the endogenous inflammatory mechanisms that create collateral damage are coaxed into the ideal state to protect and promote neuronal regrowth and functional recovery.

ABSTRACT

In molecular-genetic research of stroke, candidate gene association studies, linkage studies and genome-wide association studies have proved the role of genetic factors as risk factors for the development of ischemic stroke. This research had been initiated approximately 1.5 decade ago, and three major blocks of research approaches can be separated. In the first wave of trials the classic susceptibility markers discovered originally in relation of other diseases like cardio vascular disease, affecting different pathways, such as the inflammatory and haemostatic system, homocysteine metabolism and the renin–angiotensin-aldosterone system were tested also for stroke. Very numerous reports had been presented about the “classical” factors in different populations; the articles used biobanks with just a couple of hundreds or even less samples. In the second and still ongoing group, which is a kind of bridge between the two other blocks of studies, the spectrum of candidate genes rapidly increased, functional variants of genes or genomic regions still discovered primarily in relation to other diseases, were tested on larger stroke biobanks of clinically better stratified patients, large number of these alleles were originally discovered by array based genome-wide association studies. The third period of research had been started with the dramatic spread of the direct array screening of the large biobank samples; this approach represent still a huge significance in the further progress. What we learned is that the careful stratification of patients is critical and obligatory; the susceptibility alleles are often shared; not all susceptibility factors, that associate with clinical traits that can be itself a risk factor to stroke (like increase of

triglycerides), are necessarily represent susceptibility for stroke. The studies still mainly focus on large and small vessel associated stroke, and the knowledge on other types of stroke which represent much smaller population samples are still very scarce. Albeit some susceptibility allele tests are on the palette of some direct-to-consumer (DTC) companies, the clinical utility and clinical validity of these test results still does not support their use in the patient care.

OVERVIEW OF STROKES

According to the definition of the World Health Organization (WHO) stroke is a suddenly developing temporary, or in unfavorable cases permanent damage of the brain. This definition has been used for more than 20 years in the clinical practice to describe this heterogeneous condition. [140;142] It can affect both males and females at any time of life; however, it is more prevalent in males over 45 years of age. [27]

The disease can be classified into two subgroups: hemorrhagic and ischemic stroke. Ischemic stroke comprises 80-85% of all stroke cases; 15-20% of the cases are hemorrhagic, like intracerebral or subarachnoid. Various pathophysiological mechanisms can result in ischemic stroke. Ischemic stroke can be a result of atherothrombosis (75% of cases) or embolism (25% of cases) leading to occlusions in arteries. However, 30% of ischemic strokes can be form from other causes, like systemic hypoperfusion.

Acute ischemic stroke is the leading cause of death and the most commons cause of disability in the developed countries [111]. In incidence, prevalence, and mortality of stroke huge differences can be seen among countries worldwide. The incidence rates of stroke in the US have been proven to be the highest in the world with 795,000 cases annually; 150,000 deaths occurred in 2011. The prevalence rate was approximately 5.8 million, of which 87% was ischemic stroke. In Japan, stroke is also a major public health problem; the prevalence rate of stroke was about 1.4 million in 2005, of which 61% was ischemic. [144] In Europe, stroke has similar epidemiology rate; the incidence of stroke is less in European populations than in the US. The observation of an epidemiological review there are large geographical variations in the incidence of stroke, which show decreasing gradient from eastern to western European countries: among the examined populations, the incidence of stroke was the highest in the Russian populations: 600,000 annually as against 210,000 per year in French in 2007. [126]

STRATIFICATION OF ISCHEMIC STROKE

The stringent classification of subtypes of ischemic stroke is undoubtedly critical from the viewpoint of its etiology. It can be divided into three major subgroups depending on the *pathogenic* mechanisms: thrombotic, embolic and hemodynamic stroke, which is a broadly accepted stratification of ischemic stroke. This classification is based on results received by imaging examinations. These groups can overlap and are not necessarily specific enough. However, the exact determination of subgroups cannot be ignored in point of prevention and its treatment.

The first major *clinical* classification was introduced in 1991 with the Oxford Community Stroke Project [8], which was followed by a more widely accepted one in 1993. This was based on the most common pathophysiological mechanisms involved in the development of stroke: Trial of Org10172 in Acute Ischemic Stroke (TOAST). The system comprises five subgroups: 1) large-vessel atherosclerotic type, in which patients have cortical or cerebellar lesions and/or brainstem infarcts or subcortical hemispheric infarcts greater than 1.5 cm in diameter on magnetic resonance imaging (MRI), with or without cerebral cortical impairment or brainstem or cerebellar dysfunction; 2) small-vessel occlusion type: patients with one or more subcortical hemispheric or brainstem infarcts with a diameter <1.5 cm on MRI, with one of the features of the traditional clinical lacunar syndrome and without cerebral cortical dysfunction 3) cardioembolic subtype comprises patients with arterial occlusions presumably due to an embolus arising in the heart; 4) stroke with other determined etiology, which includes patients with rare causes of stroke like hematologic disorders, nonatherosclerotic vasculopathies and hypercoagulable states; 5) stroke with unidentified etiology, in which the cause of stroke cannot be determined. [3]

RISK FACTORS FOR STROKE

Stroke is a multifactorial disease. Environmental factors can have crucial role in the development of the disease. Several risk factors were identified in the development of ischemic stroke, which were categorized as potentially modifiable and non-modifiable ones. [18;68;116]. Thus, age and gender were enrolled into non-modifiable risk factors; besides previous stroke in case history, which increases considerably the probability of subsequent cerebrovascular event, can also be enrolled into non-modifiable risk factors.

Hypertension, diabetes mellitus, obesity, elevated triglyceride- and cholesterol levels, smoking, exaggerated alcohol consumption and presence of any cardiovascular events like atrial fibrillation, myocardial infarction, carotid stenosis are categorized as modifiable risk factors in this classification. These factors proved to be unambiguous risk factor for the development of disease, so control of these risk factors compose part of primary prevention strategies. Recently, additional possible risk factors like several naturally occurring variants within the genome came into the focus of epidemiological studies. So far a significant progression could be observed in the identification of genetic variants in the background of stroke, and other cerebro- and cardiovascular disorders. [5;23;29;42;87]. Investigation of these variants provides novel approach to the knowledge of pathogenesis of conditions.

MONOGENIC DISORDERS ASSOCIATED WITH ISCHEMIC STROKE

Cerebral Autosomal Dominant Arteriopathy with Subcortical Infarcts and Leucoencephalopathy (CADASIL)

CADASIL is a heritable stroke associated disease caused by mutations in the NOTCH3 gene [57]. However, not-all patients with this clinical phenotype have a NOTCH3 mutation [96]. The clinical phenotype comprises multiple lacunar strokes and transient ischemic

attacks, migraines with aura and ultimately, cognitive impairment due to vascular dementia with usually onset in the third to sixth decade [24]. A relatively unique but not pathognomic diagnostically important feature of the disease is the bilateral white matter involvement of the anterior temporal lobes and the external capsules [6;93].

The gene encodes cell-surface receptor which is expressed on vascular smooth muscle cells. The receptor is a heterodimer with a large extracellular domain containing epidermal-growth-factor-like repeat domains. Mutations usually occur in the 2 to 24 exons of the gene, resulting in a change of the number of cysteine residues [58;106]. Despite that the mutation spectrum being broad, the genotype seems to have no major impact on the phenotype. The underlying mechanism of the disease is poorly understood. The most specific and sensitive diagnostic method is skin biopsy. Multiple studies showed that, patient despite the nature of their NOTCH3 mutation, had granular osmiophilic deposits within their vascular basal lamina [114;139].

A recent 7-year long longitudinal study of 25 NOTCH3 mutation carrier CADASIL-patients, came to the realization: that the cognitive decline is rather to be associated with lacunar strokes, microbleeds and increased ventricular volume than white matter changes shown on MRI [67]. A recent monozygotic twin study pointed out the importance of environmental factors in the disease. The twin who smoked and had a sedentary life style suffered a stroke 14 years sooner than the twin with a healthy life style [89].

Cerebral Autosomal-Recessive Arteriopathy with Subcortical Infarcts and Leukoencephalopathy (CARASIL)

CARASIL is a cerebral small-vessel arteriopathy transmitted in an autosomal recessive manner. Typical clinical features are normotension, alopecia, strokes and eventually dementia with onset in the first 3 decades [30]. The genetic background of the disease, are mutations affecting the HtrA serine protease 1 (HTRA1) gene [40].

Fabry's Disease

Fabry's disease is an X-linked metabolic disorder caused by the deficiency of lysosomal enzyme α -galactosidase A. The insufficient enzyme activity is associated with accumulation of glycosphingolipids mainly in the heart, kidneys, eyes, skin and the vascular system. Clinical symptoms include acroparesthesia, anhidrosis, corneal opacities, cataracts, angiokeratomas, and renal, cardiac failure with a typically childhood or adolescent onset [28]. Cerebrovascular events occur from both large and small vessel disease, frequently affection the regions supplied by the posterior circulation [36;112].

However, only small vessel involvement is associated with white matter changes. Manifestations of Fabry's disease been also reported in heterozygote female carriers of the mutation, with clinical features ranging from asymptomatic, mild manifestations to rare cases showing severe disease as in affected males [22]. The disease can be confirmed with enzyme activity measurement however, the method in women is less reliable due to the skewed inactivation of the X chromosome.

The prevalence of the disease was surprisingly high in young stroke patients according to a German study, suggesting 4.9% of all cases to be GLA mutation being the underlying cause of cryptogenic ischemic stroke in young men [112]. Recent US studies however, showed differ. The Stroke Prevention in Young Men Study observed Fabry's disease in 0.18% of all strokes, and 0.65% of cryptogenic strokes [151].

Therapy of the disease involves enzyme replacement therapy. Recent studies showed that the enzyme replacement therapy, according to a five-year data report, proved to be significantly reducing the pain and life quality of Fabry patients. Treatment also seems to act favorable in cardiac parameters, including left ventricular mass reduction and an increase in midwall fraction shortening [81].

Sickle-Cell Disease

Sickle-cell disease is the most common cause of ischemic stroke in children [128]. The underlying cause of the disease can be a homozygous state for hemoglobin S, or a compound heterozygous state associated with other types of hemoglobinopathies such as hemoglobin C or α -thalassemia [95]. Hemoglobin S carriers have a point mutation in the β -globin chain of hemoglobin, causing the hydrophilic amino acid glutamic acid to be replaced with the hydrophobic amino acid valine at the sixth position.

This change, under low-oxygen condition promotes a non-covalent polymerization (aggregation) of hemoglobin thus creating the critical component of the pathogenesis of the disease, namely abnormal vessel-red blood cell interaction with increased thrombus formation [128]. Homozygous carriers have approximately 25% chance of developing stroke before the age of 45 [94]. The incidence for stroke is highest between 2-5 years and stroke recurrence is common.

Clinically manifested strokes are usually associated with large vessel involvement, and are typically located to the borderzone regions [99]. The risk of stroke in sickle-cell disease is strongly affected by the genotype of the affected patients. Polymorphisms in the fetal hemoglobin gene, in cell-adhesion molecules VCAM and P-selectin or variations in the interleukin 4 receptor gene may greatly modify the clinical outcome of the disease [25;49;120;138].

Mitochondrial Myopathy, Encephalopathy, Lactic Acidosis, and Stroke-Like Episodes (MELAS)

MELAS is a syndrome characterized by developmental delay, hearing loss, short stature, seizures, vomiting, diabetes, migraine and cognitive decline [23]. The onset of the disease is usually in childhood initially characterized by tonic-clonic seizures, headache and vomiting. MELAS is associated with several mitochondrial mutations [78;100].

The most frequent mutation is a adenine to guanine change at position 3243 in the tRNA^{Leu}(UUR). The second most common (T3271C) is the genetic background in 10% of all cases. In MELAS the cortex is almost always involved in stroke like episodes, and lesions do not limit to vascular territories, since the underlying cause is an energetic imbalance instead of vascular occlusion [30].

Homocystinuria

Homocystinuria is a mostly recessively inherited enzyme deficiency related disease characterized by high levels of plasma homocysteine and homocystinuria. Clinical features of the disease are mental retardation, atraumatic lens dislocation, Marfan-like skeletal abnormalities and thrombotic events including stroke [23]. Most common cause of the disease is a deficiency of cystathion beta-synthase (CBS); however, the mutation spectrum is broad [66]. Half of untreated patients have thrombotic events by the age of 30 and some of these cases result in stroke [88]. Mechanism of stroke can be either thrombotic, small vessel related or due to arterial dissection [41;62]. Concurrent Leiden mutation raises thrombosis risk [74]. B6 vitamin therapy responding patient have generally better prognosis, and milder symptoms compared to non responders [154].

Moyamoya Disease

Moyamoya disease is a chronic progressive, occlusive, cerebrovascular arteriopathy characterised by bilateral stenosis of distal carotid vessels with frequent feature of telangiectic vessel changes of the circle of Willis [122]. The disease is rare in non-Asian population however, its prevalence in Japan is estimated 3/100000 [122].

The disease may manifest both in childhood with clinical symptoms of transient ischemic attacks, strokes and epilepsy [23], or in adult with symptoms raising from rupture of telangiectic vessels developed during childhood [7]. 10% of all cases occur as familial cases, however, the pattern of hereditary of the disease is not well understood [31]. Both autosomal dominant and polygenic mode of transmission with incomplete penetrance have been suggested [23;122]. The disease has been mapped to loci for the ch3p (MYMY1), variations in the RNF213 gene on ch17q25 confer susceptibility to (MYMY2) and ch8q23 (MYMY3), while (MYMY5) is caused by mutation in the ACTA2 gene on ch10q23.3.

Finally, an X-linked recessive syndromic disorder characterized by the Moyamoya phenotype, short stature, hypergonadotropic hypogonadism and facial dysmorphism has been identified in patients of three unrelated families (MYMY4). The deleted region identified on chXq28 and included exon 1 of the MTCP1/MTCP1NB gene and the first three exons of the BRCC3 gene [23;53;86;117;153]. Moyamoya may be also secondary or associated with other disease like: sickle-cell anemia, pseudoxanthoma elasticum, hemoglobinopathies, Down's syndrome, neurofibromatosis type I, William's syndrome, Graves disease and neurofibromatosis type I [23;122;125].

Marfan's Syndrome

Marfan syndrome is an autosomal dominantly inherited disease affecting the musculoskeletal system, cardiovascular system and the eye [59]. Other clinical features of the disease consist of chest deformities including both pectum excavatum and carinatum, scoliosis, lens deformities including luxation of the lens, arachnodactylia, generally long limbs (upper to lower segment ratio <0.86, or arm to height ratio >1.5), however the most serious complication is the dilation and/or dissection of the aorta [2;20;23;59].

Table 1. Classification of stroke subtypes

Classification	Reference
Trial of Org10172 in Acute Ischemic Stroke (TOAST)	[3]
large-artery atherosclerosis (embolus/thrombosis)*	
cardioembolism (high-risk/medium-risk)*	
small-vessel occlusion (lacune)*	
stroke of other determined etiology*	
stroke of undetermined etiology	
two or more causes identified	
negative evaluation	
incomplete evaluation	

*Possible or probable depending on results of ancillary studies.

Genetic background of the disease are mutations in the very large gene of FBN1 (65exons), encoding fibrillin-1, an extracellular matrix protein.

Diagnosis of the disease is usually a clinical one [20], since the mutation spectrum is broad and direct sequencing of the gene is rather expensive and laborious [91]. There is increased evidence that fibrillin-1 shares homology with TGF binding proteins, thus TGF might play a key role in the development of the disease [59;90]. Ischemic strokes and subdural hematomas both can be both manifestations of cerebrovascular complications of the disease; however the underlying mechanism is not well understood. A retrospective study associated these complications with embolisms, originating from the heart, in particular mitral valve prolapse, atrial fibrillation and prosthetic valves. The study involved 513 patients and found no association with aortic disease or cerebral vessel dissection [150]. However, others observed association of cerebrovascular events associated with vessel dissection [119;124], and there have been reports of strokes in patients taking chronic anticoagulant therapy and perioperative embolic cases in patients undergoing aortic replacement surgery [33].

Ehlers-Danlos Syndrome

Ehlers-Danlos syndrome is a group inherited disease mostly affecting the connective tissues and caused by mutations in genes responsible for coding collagen (Type-I or Type-III). From the different types of the disease, the autosomal dominantly inherited Type-III is the one where cerebrovascular complications like large and medium-sized artery rupture, intracranial aneurysms and arterial dissection are common [92;119]. Phenotypic features of the disease include characteristic facial appearance (big eyes, lobeless ears, thin nose and lips, sunken cheeks), small stature with a slim body, thin-translucent skin with visible veins specially over the chest and abdomen, and due to the fragile vessels, easy bruising and rupture of other organs like the uterus or the intestines [9].

The genetic background of the disease is mutations in the COL3A1 gene (encoding collagen Type III) with a broad mutation spectrum [105]. Neomutations are common and only 50% of all cases have a positive family history [105]. In a clinical study of 419 patients, 11% had neurovascular complications [105].

PERIODS IN THE STROKE SUSCEPTIBILITY RESEARCH

The Classic Genetic Risk Factors and the Stroke

At the beginning of genetic background's research of stroke, examinations of single genetic variants had been carried out, which might be involved in the possible pathogenic mechanisms of this condition. This period, which can be regarded as the first wave in the stroke research, was otherwise the beginning of the susceptibility allele research for numerous other multifactorial diseases, including ischemic heart disease, type 2 diabetes, and metabolic syndrome, as well. Among these, several polymorphisms of genes encoding enzymes involved in the renin-angiotensin system, nitric-oxide production; and of genes influencing hemostasis, homocysteine- metabolism are shown in Table 2 and Table 3.

Disturbance of balance of hemostasis can lead to increased aggregation of blood platelets, thrombus formation, which may results from defects of genes encoding components of coagulation cascade like factor II, V, XIII and fibrinogen promoting development of several cardio- and cerebrovascular phenotype. Activated factor V acts as a cofactor for the conversion of prothrombin to thrombin.

In the F5 gene, c.1691G>A transition (p.Arg506Gln) was first identified by Bertina and co-workers in a family with thrombophilia in 1994. [10] The c.1691G>A alteration has been reported to be associated with resistance to degradation by activated protein C. Since then, numerous studies were engaged in examining this variant in several conditions in correlation with thromboembolism, whose results were inconsistent regarding the pathological role of this alteration. [4;15;19;109]

Table 2. Genetic-association studies: genes and their polymorphisms identified in the background of ischemic stroke

Gene	Polymorphism	Reference
hemostasis		
II. factor (prothrombin) (+176930)	c.20210G>A	[14;21;77;108]
V. factor (Leiden) (*612309)	p.Arg506Gln	[4;10;14;15;19;109;110;134]
XIII. factor (+134570)	p.Val34Leu	[14;16;32]

inflammation		
ALOX5AP (*603700)	7 SNPs, haplotypes	[45;46;69;85;156]

Abbreviations: ALOX5AP: arachidonate 5-lipoxygenase-activating protein; APOA5; CIII: apolipoprotein A5; -CIII proteins; Arg: arginine; Asn: asparagine; LPL: lipoprotein lipase; OMIM: <http://www.ncbi.nlm.nih.gov/sites/entrez?db=OMIM>; PDE4D: phosphodiesterase 4D.

According to achievements of a large-scale epidemiologic assessment, carriage of 1691A allele was not associated with an increased risk of stroke. [110] However, statistically significant association was found between the presence of c.1691G>A transition and ischemic stroke in a meta-analyses. [14] Szolnoki and co-workers found that c.1691G>A alteration does not confer risk for stroke alone, but in combination with other unfavorable factors like hypertension or diabetes mellitus can increase the relative risk of ischemic stroke. [134]

The most extensively studied alteration of prothrombin (factor II) gene is c.20210G>A, which was first described in 1996. [108] This sequence variation is associated with elevated prothrombin levels. Several studies found a statistically significant association between ischemic stroke and this substitution [21;77]; the data of a meta-analysis also suggest that c.20210G>A variant is a risk factor for ischemic stroke. [14]

The susceptibility role of p.Val34Leu substitution in factor XIII encoding gene remains ambiguous according to the findings of association studies. [16;32] The meta-analysis of Casas and colleagues suggest that p.Val34Leu variant does not confer increased risk for development of stroke. [14]

The c.455G>A alteration of fibrinogen encoding gene have been found to occur more frequent in homozygous form in large-vessel stroke subgroup. [63] Carrying the rare allele causes elevated fibrinogen levels, which confer susceptibility to ischemic stroke via prothrombotic mechanisms. Similar relationship was found for other variants of fibrinogen, however, only in female patients, which mechanism is unclear yet. [13]

The renin-angiotensin system regulates the hypertension and water balance. When hypotension occurs, renin is secreted from the kidneys, which protease cleaves angiotensinogen converting angiotensin I. This intermedier forms into angiotensin II catalyzed by angiotensin converting enzyme (ACE). This enzyme encoding gene located on chromosome 17 is one of the most intensively studied candidate gene in association with ischemic stroke. Cambien and colleagues have first described the insertion/deletion

polymorphism (I/D) of the gene in myocardial infarction. [12] Six years later, a meta-analysis reported significant positive association between deletion polymorphism of ACE gene and ischemic stroke. [121] The results of a large, prospective study indicate that the ACE I/D polymorphism is not associated with subsequent risk of stroke. [157] In a Hungarian population ACE D/D confers risk for development of stroke. [133;134] Subsequent studies tended to variant of I type of angiotensin II receptor encoding gene (AT1R c.1166A>C). The AGTR1 has multiple effects, both cardiac and systemic, mediating vasoconstriction, cellular hypertrophy and catecholamine release. In a Caucasian population weak association was found between carrying 1166C allelic variant and stroke. [11;113] According to the results of Szolnoki and colleagues 1166C allelic variant represents susceptibility to the disease in hypertensive smokers. [130] Co-occurrence of ACE I/D and AT1R c.1166A>C variants was found to confer risk for small-vessel occlusion type in Hungarian population. [132] Several studies have investigated ACE I/D polymorphisms in association with numerous conditions, but its role remains controversial. It has been delineated that ACE D/D polymorphism contributes to the development of atherosclerotic mechanisms, which can be modified by gene-gene and/or gene-environmental interactions.

The nitric-oxide-synthase system is an important regulator of integrity and growth of vascular endothelium and is an ubiquitous molecule responsible for the maintenance of normal endothelial function. The key enzyme is the endothelial nitric-oxide-synthase (ENOS), which converts L-arginine to L-citrulline generating nitric-oxide (NO) in the arteries, and has role in the vasodilatation. Under pathologic conditions superoxide has arisen instead of NO in the cells, which can initiate atherosclerotic process. Defects in the gene encoding ENOS was found in the background of pathological functions. In 1996, Wang and colleagues identified a functional variant (enos4a/b) of ENOS encoding gene in association with coronary artery disease (CAD) first in the literature. [143] Since then there are few reports on candidate variants in ENOS gene in association with ischemic stroke. Howard and colleagues found that promoter region polymorphism (-786T>C) of ENOS gene is associated with ischemic stroke susceptibility in young black women. [50] Another SNP in this gene (c.894G>T) has been shown not to be a susceptibility factor for ischemic stroke, however, co-occurrence with other SNPs like ACE D/D, MTHFR c.677C>T could increase stroke risk. [129]

Hyperhomocysteinemia caused by pathological homocysteine metabolism have been shown to be associated with increased risk for several cardio- and cerebrovascular events. Elevated homocysteine levels can be resulted from reduction of 5,10-methylenetetrahydrofolate reductase (MTHFR) enzyme activity, which catalyses the methylation of homocysteine. Extraordinary, complete absence of MTHFR enzyme was also observed. Variants in MTHFR gene (c.677C>T, c.1298A>C) can lead to deficiencies in the enzyme activity. The c.677C>T alteration was found to represent an important risk for cerebral events. Examinations of these polymorphisms revealed no association between carriage of 677T or 1298C alleles and development of stroke. [21;75] However, Szolnoki and co-workers stated later that co-occurrence of these two alleles confer susceptibility to ischemic stroke both in hetero- and homozygous form. [135] A case-control study demonstrated that 677T allelic variant is more prevalent in ischemic stroke patients in co-occurrence with AT1R c.1166A>C variant; and they confer together increased risk for stroke. [131]

Apolipoprotein E, the main apoprotein in chylomicrons, serves as a ligand for cellular receptors on liver and peripheral cells and interacts with proteoglycans on the endothelium

guiding lipoproteins to lipases. The APOE gene located on chromosome 19 is polymorphic with three codominant alleles $\epsilon 2$, $\epsilon 3$ and $\epsilon 4$ defining six genotypes. [141] Carriers of the $\epsilon 2$ alleles have been associated with lower total and LDL-cholesterol levels, as well as elevated triglyceride levels. Carriers of the $\epsilon 4$ allele have increased levels of both total and LDL-cholesterol compared to $\epsilon 3/\epsilon 3$ homozygotes. [26] A dozens of studies have delineated that APOE is an important predicting factor for the development of ischemic stroke. [17;63;76] At 10-year follow-up study by Kathiresan, the genotype data confirmed this association. [60] Szolnoki and co-workers observed that APOE $\epsilon 4$ allele alone represents a minor genetic risk factor for ischemic stroke. However, co-occurrence of APOE $\epsilon 4$ allele and traditional risk factors like hypertension, diabetes mellitus, smoking and alcohol consumption represents considerably elevated risk for ischemic stroke. [134]

Further Search for the Functional SNPs in Stroke

In the next period of the stroke research there was a great step ahead, as the profile of the functional variants as possible susceptibility genes was increased very rapidly. Increased concentrations of plasma lipids, triglyceride and cholesterol levels were found to be independent risk factors for cardio- and cerebrovascular disorders. [47;48;73] Plasma triglyceride levels are determined by numerous genes and their interactions with the environment. Search for the genetic variations affecting plasma triglyceride concentrations is still ongoing, several loci were identified so far include APOAI/CIII/AIV, APOA5 and LPL. [60;148]

The apolipoproteins are lipid binding proteins, involved in the plasma transport of lipids. Genetic variations influencing their protein structure or synthesis may affect lipid metabolism resulting in progression to cardio- and cerebrovascular disorders. A gene cluster was identified on chromosome 11, which contains APOAI, APOCIII, APOAIV genes. [37] Apolipoprotein CIII (APOCIII) encodes a protein of 79 amino acids that is synthesized in the liver and the intestines and which is an essential constituent of circulating particles rich like VLDL and chylomicrons. [56] Several polymorphisms of apolipoprotein CIII (APOCIII) have been associated with hypertriglyceridemia. [137] Carriers of the G allele of the c.3238C>G polymorphism of APOCIII 3'-UTR were reported to have higher plasma triglyceride concentrations, as do individuals with two minor alleles, -482C>T and -455T>C of the APOCIII promoter. [145;146] Since ApoCIII inhibits the hydrolysis of triglyceride-rich particles by lipoprotein lipase, its overexpression leads to hypertriglyceridemia. [56] Only a few studies were engaged in exploring the role of APOCIII gene SstI polymorphism in the development of ischemic stroke. Aalto-Setälä and colleagues found a negative association between APOCIII polymorphism and ischemic stroke. [1]

The apolipoprotein A5 (APOA5) gene is located near the APOAI/APOCIII/APOAIV cluster encoding 366 amino acids. [101] The mature APOA5 protein is synthesized in the liver and thereafter is secreted into the plasma. [147] Evidence supports that APOA5 plays a central regulatory role in triglyceride metabolism through the inhibition of hepatic VLDL production or by guiding VLDL and chylomicrons to proteoglycan-bound lipoprotein lipase. [83;84] Furthermore, APOA5 has been described to independently influence plasma triglyceride levels in an opposing manner than APOCIII. [115] Around 40 polymorphisms of the APOA5 gene have been identified since the discovery of the gene. [52;103;136] These

natural variants may alter the function of the protein. The most common natural variants, -1131T>C (rs662799) in the promoter region, g.1259T>C (rs2266788) in 3'UTR region, c.56C>G (with Ser to Trp amino acid change in the signal peptid, rs3135506), and intronic g.IVS3+476G>A (rs2072560) have been repeatedly reported to associate with elevated triglyceride levels. [101-103] Some of them were also found to be independent risk factors for several conditions associated to triglyceride metabolism. The carriage of -1131C and g.IVS3+476A mutant alleles have been established to confer increased risk for all subtype of ischemic stroke. [43;71] 56G allele was found to associate with only large-vessel stroke in Hungarian subjects. [72] In contrary, 1259C variant did not represent increased risk for the disease. [71] The most common SNPs of APOA5 gene are in strong linkage disequilibrium and constitute haplotype variants (APOA5*2,*3,*4,*5). Among these APOA5*2 was ascertained to be a risk factor for ischemic stroke. Otherwise, APOA5 is an example for the shared susceptibility nature: the naturally occurring variant and haplotypes have been found to confer susceptibility to other diseases like metabolic syndrome. [64;65;70]

Another important factor of triglyceride metabolism is the lipoprotein-lipase (LPL), which catalyses the hydrolysis of chylomicron and VLDL-associated triglycerides with ApoCII cofactor. [44] Approximately 100 polymorphisms have been described in the LPL gene. Most of these variants can lead to decreased LPL-activity, which increase plasma triglyceride levels and the risk of atherosclerosis. [82] Huang et al. found that the p.Asn291Ser alteration has significant influence on serum levels of triglycerides, but this LPL polymorphism does not contribute greatly to the overall risk of ischemic stroke. [51] The results of a subsequent study suggest that the p.Asn291Ser substitution is not associated with ischemic stroke in men but that it possibly confers a two-fold risk in women. [149]

The cAMP-specific 3',5'-cyclic phosphodiesterase 4D (PDE4D) is an important regulator of proliferation of smooth muscle cells and macrophages by degrading a key signaling molecule, cAMP. Defects of the protein results in accumulation of cAMP in various cell types like monocytes, and T-lymphocytes. It can inhibit immune functions like proliferation and cytokine secretion, which could generate atherosclerosis and plaque instability. The gene located on chromosome 5 encoding PDE4D was identified by Gretarsdottir in 2003. [35] Among the 260 SNP examined by the authors, six have been found to be associated with stroke. Besides, analyses of haplotypes showed significant correlation between certain haplotypes and ischemic stroke, as well. Since then 16 replication studies have been published on the association between SNPs in PDE4D and ischemic stroke in different populations, which presented various results. Some of them confirmed the previously described positive association, but there are studies, which disputes the presence of association. [69;80;85;155] The inconsistent findings among the studies can be originated in differences between population sample and ethnicity.

Beside PDE4D, arachidonate 5-lipoxygenase-activating protein encoding gene (ALOX5AP) came into the center of interest of association studies. The gene encodes a proinflammatory mediator, which is implicated in the pathogenesis and progression of atherosclerosis. Several polymorphisms and haplotypes were identified in the ALOX5AP gene, which have been shown to confer increased risk for stroke in Icelandic population. [46] This result was confirmed in German and Scottish population. [45;156] However, some studies found no association between the presence of polymorphisms in ALOX5AP and clinical phenotypes. [69;85] Investigation of functional consequences of these variants has just begun.

Interestingly, the spread of the genome-wide association studies reached first other diseases, like the Parkinson's disease, myocardial infarction, inflammatory bowel disease including, or even relatively rare conditions like the macular degeneration, the stroke disease was involved secondarily, as several SNPs discovered originally in relation with other diseases, were also tested in stroke biobanks. Thus, variant discovered in genome-wide association studies, focused on alleles involved in triglyceride metabolism, a variant (rs780094) of the glucokinase regulatory protein (GCKR), which associate with increased triglyceride levels was also investigated. [60;148] The GCKR gene, located on chromosome 2 encodes a protein of 625 amino acids. GCKR protein inhibits glucokinase in liver and pancreatic cells by binding the enzyme non-covalently to form an inactive complex. Jaromi et al. investigated the GCKR c.1337C>T (rs1260326) variant in a case-control study on stratified stroke population. No association could be detected between GCKR alleles and triglyceride levels or with the susceptibility to stroke. [55]

Single nucleotide polymorphisms localized at the GALNT2 and MLXIPL/TBL2 loci have also been found to be associated with increased triglyceride level by GWA studies. [60;148] The rs4846914 is an intronic variant of the UDP-N-acetyl-alpha-D-galactosamine:polypeptide N-acetylgalactosaminyltransferase 2 (GALNT2) gene, and its minor G allele was reported to associate with higher triglyceride concentrations. The GALNT2 gene is responsible for the transfer of an N-acetyl galactosamine to the hydroxyl group of a serine or threonine residue in the first step of O-linked oligosaccharide biosynthesis. A Hungarian case-control study evaluated the association of GALNT2 rs4846914 variant with triglyceride levels, and explored their possible contribution to the development of ischemic stroke.

No positive association was detected either with triglyceride levels or with susceptibility to the disease. [55] The major alleles of rs17145738 and rs3812316 variants within the MLXIPL/TBL2 region have been found to be associated with increased triglyceride levels. [60;148] MLXIPL encodes a transcription factor, MXL interacting protein-like which plays a role in the activation of carbohydrate response element motifs in the promoter region of genes involved in lipogenesis and triglyceride synthesis, and regulates lipogenesis and glucose utilization in the liver. TBL2 encodes transducin beta-like 2 protein which is thought to be involved in intracellular signaling. Polgar and co-workers examined the possible susceptibility nature and the effect of rs17145738 and rs3812316 variants on triglyceride levels. The results showed that presence of these variants did not result in elevated triglyceride levels and did not confer risk for ischemic stroke. [107]

Direct Genome-Wide Association Studies in Ischemic Stroke Biobanks

The first GWAS directly done in ischemic stroke patients was published in 2007 [79]; in this year the GWAS was announced as breakthrough of the year by the Science magazine. [104] The GWA studies in association with ischemic stroke are summarized in *Table 4*. Matarín and colleagues analyzed 278 ischemic stroke patients and 275 controls for more than 408,000 unique SNP using Illumina Infinium Human-1 and HumanHap300 assays. The ischemic stroke subtypes were allocated according to the specified TOAST classification.

Table 4. Genome-Wide Association Studies in stroke

Population	Sample size	Sample size in replication	Number of SNPs examined	Number of SNPs examined in replication	Positive association		Platform	Reference
					Gene	Variant		
Caucasian	19,602 individuals	3656 cases, 3613 controls	2,194,468	2	near NINJ2 and WNK1 genes	rs11833579 rs12425791	Affymetrix and Illumina	[54]
Japanese	6,341 individuals	705 cases, 3426 controls	520,000	100	CELSR1 (*604523)	rs6007897 rs4044210	Affymetrix	[152]
Caucasian	1,661 cases, 10,815 controls	2224 cases, 2583 controls/ 2327 cases, 16760 controls	310,881	120/2	near PITX2 (*601542)	rs2200733 rs10033464	Illumina	[34]
US	249 cases, 268 controls	-	408,000	-	IMPA2 (*605922) KCNIP4 (*608182) KCNK17 (*607370)	rs7506045	Illumina	[79]

Abbreviations: CELSR1: cadherin EGF LAG seven-pass G-type receptor 1; IMPA2: inositol(myo)-1(or 4)-monophosphatase 2; KCNIP4: Kv channel interacting protein 4; KCNK17: potassium channel, subfamily K, member 17; NINJ2: Nerve injury-induced protein 2; PITX2: paired-like homeodomain 2.

The results showed hundreds of nominally statistically significant associated markers, of them notable candidate loci are IMPA2 on chromosome 18, KCNIP4 on chromosome 4, KCNK17 gene chromosome 6, which are involved in the phosphatidylinositol signaling pathways and potassium transport, respectively. [79]

In 2008, Gretarsdottir described the results of a well-powered GWA study with 1,661 ischemic stroke patients from the Icelandic population classified according to TOAST and 10,815 controls. The authors used Illumina Infinium Human-1 and HumanHap300 chips for genome-wide genotyping containing more than 310,000 SNPs.

From these, 20 SNPs were selected for replication. Of those, rs2200733 and rs10033464 in the transcriptional activator encoding PITX gene on chromosome 4q25 segment have been found to associate significantly with development of ischemic stroke, especially for stroke due to cardioembolism (cardiogenic stroke). [34] Some variants identified in the gene have been found to be associated with Axenfeld-Rieger syndrome previously. [123;127]

A Japanese GWAS, which called 6,341 participants (992 IS patients and 5,349 controls) to the study, analyzed more than 520,000 SNP applying GeneChip Human Mapping 500K Array by Affymetrix.

After receiving results Yamada and colleagues selected 100 SNPs for replication study. According to the results polymorphisms in the CELSR1 gene on chromosome 22 have been found to be susceptibility gene for ischemic stroke. The CELSR1 gene encodes a transmembrane G protein-coupled receptor. [152]

Combined analysis of genome-wide association study data generated from four large cohorts (Framingham Heart Study, Rotterdam Study, ARIC and Cardiovascular Health Study) was carried out by Ikram et al. The cohorts include 19,602 applicants, of whom 1164 suffered from one of the ischemic stroke subdivided into atherothrombotic and cardioembolic subtypes.

The genotyping was performed with different platforms (Affymetrix GeneChip SNP Array 6.0, GeneChip Human Mapping 500K Array and 50K Human Gene Focused Panel; Illumina HumanCNV370-Duo and Infinium HumanHap550 3.0). Two of the analyzed SNPs, rs11833579 and rs12415791 on chromosome 12 near NINJ2 and WNK1 genes, are implicated into replication study, which revealed positive association between carrying minor alleles and ischemic stroke, in particular, atherothrombotic stroke subtype. [54]

The spectrum is still growing, and the major achievements can be found at the website of the National Institutes of Health (<http://www.nih.gov/>).

Beside its huge power and impact, the GWA studies have also known limitations. In a few cases individuals involved into the study derived from one population. The validation of their findings will be required in other independent ethnic groups.

In certain replication studies, the number of subjects was too small and functional relevance of the identified polymorphisms remains unclear. So further genotyping, detailed functional and epidemiological studies in a greater population are required to identify the exact role and associations of these genes and gene variants with conditions.

CONCLUDING REMARKS

In the past almost 2 decades a significant progression has been made in the stroke susceptibility genetics. Clear imbalance can be observed: while some major types of the diseases, like the large- and small vessel pathology associated types are intensively investigated, the less frequent forms escaped the focus. It is clear now that the careful stratification of patients is critical and obligatory for research purposes. Several genes or susceptibility alleles are often shared.

It is also clear, that some susceptibility factors that associate with clinical traits that can be itself a risk factor to stroke, as they associate with increased triglycerides, are necessarily represent susceptibility for stroke. Since the role of abnormalities of several laboratory, and biochemical parameters is uncertain in the development of ischemic stroke, growing knowledge about their nature will help the understanding also their role in stroke.

Albeit some susceptibility allele tests are offered on the palette of some direct-to-consumer companies, the clinical utility and clinical validity of these test results still does not support their current use in the patient care. The spread of the next generation techniques will certainly open new perspective both in the monogenic and polygenic field.

Chapter 8

PERIOPERATIVE ISCHEMIC STROKE

***Richard Shek-kwan Chang*, Windsor Mak,
Raymond Tak-fai Cheung and Shu-leong Ho***

Department of Medicine, Queen Mary Hospital,
University of Hong Kong, PRC

ABSTRACT

Perioperative stroke, although uncommon, can complicate various surgical procedures leading to major consequences including mortality. In this chapter, our focus is in ischemic stroke occurring in the intra-operative and post-operative periods of non-neurological surgeries. Previously reported risk factors for perioperative stroke include a history of cerebrovascular events, chronic obstructive pulmonary disease, peripheral vascular diseases and cardiac arrhythmias. The mechanism of perioperative stroke is likely to be diverse; hence a “splitter” approach should be adopted when evaluating individual cases. Hypoperfusion is conventionally believed to be an important contributing factor in perioperative stroke. Current evidence, however, shows that its role is still controversial. Although anesthesia can induce hypotension, cerebral perfusion is seldom impaired. It is observed that watershed infarction, which is usually attributable to low blood pressure, is actually uncommon in previous case series. There are so far no good predictors for perioperative stroke. Scoring systems had been developed for stroke risk stratification, but there is no clear consensus yet in their routine applications. Various measures, including prophylactic use of statin or beta-blockers have been studied to prevent perioperative stroke.

INTRODUCTION

Perioperative stroke is an uncommon but a major complication of surgical operations with significant morbidity and mortality. Previous studies showed that perioperative stroke was a genuine clinical problem, rather than incidental events that occurred during or after

* Corresponding Author's Email: richardcsk@gmail.com.

surgery [1]. In a standard hospital, the number of surgical operations performed can be up to thousands annually. Although the incidence rate of perioperative stroke is low, the cumulative case burden is not negligible.

A substantial of patients undergoing surgery have multiple cerebrovascular risk factors, and inputs from neurologists are often needed to assess the stroke risks of surgical candidates or manage patients with perioperative stroke. Knowledge in this condition can help surgeons, anesthetists and neurologists to stratify the stroke risks in patients requiring surgery, make timely diagnosis and formulate the management plan. Moreover, by exploring the relationships among the perioperative stroke and various contributing factors, we can further understand the pathogenic mechanisms of various stroke syndromes.

In this chapter, we will limit our discussion to ischemic stroke associated with surgery, which accounts for the majority of perioperative stroke cases.

EPIDEMIOLOGY

Perioperative period is conventionally defined as the intraoperative period and a time span of 30 days after the index surgery. Stroke is defined as a focal or global neurological deficit of cerebrovascular cause that persists beyond 24 hours or is interrupted by death within 24 hours [2]. These definitions are user-friendly for diagnostic purpose. However, covert cases which are subclinical and only detectable with neuroimaging might be missed, and these patients can have resultant subtle cognitive impairment.

Currently, large scale studies to delineate the epidemiology of perioperative stroke especially in field of general surgery are lacking. The available data are mostly from relatively small or single-centered case series. The reported incidence of perioperative stroke is from less than 1% to up to around 10%, depending on the nature of intervention and whether cardiovascular procedures are included. For general surgery, the rate is less than 1%, [3] e.g., hemicolectomy 0.7%, hip replacement 0.2%, lung lobectomy or segmental resection 0.6% [4]. The incidence of perioperative stroke is about 3% for vascular surgery [5], but the risk is doubled in carotid endarterectomy [6]. The risk in head and neck surgery is 4.8% [7]. Cardiac surgery is among the highest risk groups with up to 10% risk of perioperative stroke [8, 9].

We have conducted a retrospective case-control study on perioperative stroke in our institution which is a university teaching hospital serving a population of approximate 500,000 in the southern and western districts of the Hong Kong Island. From January 2006 to July 2009, the number of non-neurosurgical operations performed was approximately 65,300 and 32 cases of perioperative stroke were identified. Each index case was matched with two control subjects in terms of age and type of surgical procedure carried. The incidence of perioperative stroke was 0.049%. This relatively low rate as compared with previous studies was probably due to the inclusion of the low risk ambulatory day cases into the analysis. Thirty-four point four percent of perioperative stroke patients underwent cardiothoracic surgery. Twenty-eight point one percent occurred in orthopedic surgery and 18.8% occurred in vascular surgery [10].

To summarize, cardiovascular procedures carry high risk because of both patient and procedural factors. Cardiopulmonary bypass carries extra embolic risk to the subject.

Vascular procedures, such as carotid endarterectomy, involve direct manipulation of the blood vessels which may result in thromboembolism to cerebral arteries. Moreover, patients with atherosclerotic vasculopathy essentially harbor various risk factors of stroke.

It is notable that most of these data were obtained from relatively small case series and were retrospective. Moreover, minor strokes with subtle clinical manifestations as well as subclinical cerebral infarcts could easily be missed and were probably not included in most of the previous studies.

Emergency procedures have been reported to be associated with a higher risk of stroke than elective operations. Patients requiring emergency operations usually have unstable systemic conditions such as sepsis, hemodynamic disturbance or organ failure [8]. The stroke onset time can range from during the intraoperative period, in which the diagnosis is usually made soon after the patients recover from general anesthesia, to two days or even weeks after the procedure (up to 30 days is the usual definition of perioperative period). The timing of perioperative stroke has been reported as bimodal. About 45% of the strokes were diagnosed within the first day after surgery and 55% were identified beyond the first postoperative day with uneventful recovery from the anesthesia [11]. Conversely, some investigators suggested most strokes occur late in the postoperative course. Hart and Hindman reported a case series of 12 patients with perioperative stroke, in whom 10 presented two days or more after the surgery [12].

PATHOGENIC MECHANISM

Hemodynamic disturbance from blood loss and hypotension induced by anesthesia during the intra- or post-operative periods could theoretically be the major culprit of stroke complication. Hence, watershed infarction from systemic blood pressure drop should have been a common perioperative stroke syndrome, and most strokes should occur intraoperatively, when the blood pressure is most liable. Nevertheless, observations from reported studies showed the contrary. Embolic stroke instead of watershed infarction was the leading cause of perioperative stroke [11, 13].

In our analysis, the majority of perioperative stroke cases (81%) were ischemic [10]. Occlusion of large arteries, probably of embolic causes, accounted for most of them, and there was only one case of watershed infarction (3%). We also analyzed the blood pressure as a stroke risk factor. Blood pressures at the time of admission and intraoperative period were studied, with equivocal results. The index cases showed greater fluctuations in some parameters only when compared with the controls. The correlation between occurrence of stroke and most of the blood pressure indices were not significant.

In a series of 61 cases of perioperative ischemic stroke after general surgery, only seven patients had watershed infarction [14]. Likosky *et al.* reported that after cardiac surgery, only 8.8% or perioperative strokes could be attributed to hypotension [15]. Embolic infarction was the commonest stroke subtype, accounting for 62.1% of all cases. Other stroke subtypes include lacunar infarction (3.1%), thrombotic stroke (1.0%), multiple etiologies (10.1%) and hemorrhagic stroke (1.0%).

Concerning the time of occurrence of embolism, researchers have monitored for the presence of embolic signals in intracranial vessels with transcranial Doppler intraoperatively

[16]. They found that the amount of embolic signals varied in different stages of cardiac surgery. The highest embolism risk occurred during the aortic cross-clamp and at the initiation of cardiopulmonary bypass. Nevertheless, the majority of the embolic strokes occur in the postoperative period remote from the surgery. Atrial fibrillation and myocardial infarction during the postoperative period are likely the main contributors to embolic stroke [14].

For non-cardiac and non-neurological operations, both thrombotic and embolic etiologies appear important. Hart and Hindman reported cardiogenic embolism was the commonest cause of perioperative stroke in general surgical procedures, accounting for 42% of all cases [12]. On the other hand, some investigators observed that the majority of perioperative stroke associated with general surgery were due to thrombosis, accounting for 68% of all cases, which was four times commoner than embolic stroke [14].

The etiology of thrombosis in perioperative stroke can be diverse. Endothelial dysfunction due to surgical stress is proposed to play a role. Unstable endothelium due to surgical stress may lead to thrombosis through various mechanisms including atherosclerotic plaque rupture and arterial spasm [17]. Besides, a hypercoagulation state is observed among surgical patients in the postoperative period. Alterations in clotting factors, platelet number and function, and fibrinolytic activity have been demonstrated. Increase in fibrinogen, activation of factor VIII, suppression of tissue plasminogen activator and decreased erythrocyte deformability all contribute to raise blood viscosity after surgery [12]. These effects can last up to weeks after the operation.

For perioperative stroke involving the vertebrobasilar circulation, there are concerns about cervical overextension leading to vertebral artery trauma [18]. In a study involving 160 patients, the effect of neck position during intubation on cerebral blood flow was investigated [19]. Magnetic Resonance Angiography was employed to monitor the blood flow changes in carotid and vertebral arterial circulation during stimulated tracheal intubation position. The results showed that posterior circulation, but not the carotid arteries, was susceptible to hyperextended neck position. This phenomenon is probably related to the anatomy of the vertebral arteries, which pass through the foramen transversarium of the transverse processes of the vertebral column. Neck angulation can result in mechanical compression on the arteries producing haemodynamical disturbance. Twenty-five percent of patients had hypoplastic vertebral arteries with low blood flow. In this patient group, basilar artery flow might be disturbed and microinfarctions were frequently found. In patients with previously unsuspected carotid and vertebral occlusion, basilar artery blood flow was also disrupted, including flow reversal, by hyperextended neck posture. Special attention to neck position should be paid for patients with known vertebral hypoplasia, vertebral occlusion or severe stenosis. A sustained neck hyperextension for more than 12 minutes seems to be a critical threshold.

Other less common pathogenic mechanisms of perioperative embolic stroke include air embolism after cardiopulmonary bypass, fat embolism after orthopedic surgery, arterial dissection and paradoxical embolism from deep vein thrombosis in patients with patent foramen ovale [11].

PROGNOSIS

Perioperative stroke is associated with poor prognosis with high mortality rate [9]. An eight-fold increase in perioperative mortality within 30 days was observed [20]. Among patients who have a history of cerebrovascular disease, mortality rates of 18% and 86% were observed [1, 14].

In our cohort, the mortality rate was 31.2% within 3 months, as compared to no post-operative death in the control group [10]. Sixty-three point three percent of perioperative stroke patients had a drop in Modified Rankin Score of 2 or greater while the same decrement was only 11% in the control group. Hence, perioperative stroke is associated with major mortality and morbidity.

Early deaths are mainly due to cerebral edema and increased intracranial pressure; late mortalities are from stroke-related complications including pneumonia, aspiration and sepsis. The high mortality may be explained by increased stroke severity for perioperative cases. The deleterious effects from ischemia tend to be accentuated by systemic inflammatory response [21]. This is precipitated post-operatively with increased levels of cytokines, including interleukin-1 and 6 and tumor necrosis factor alpha [22, 23]. The serum interleukin-6 level has been associated with brain infarct volume, 3-month clinical and stroke mortality rate outcome [24].

RISK FACTORS

Various case series had reported different risk factors for perioperative stroke. Many of them are similar to those in the non-surgical settings. We highlight some of the commonly quoted predisposing factors especially those that are specific for perioperative stroke. The risk factors can be categorised into 1) Patient, and 2) Surgical factors.

1) Patient Factors

Age and Co-morbidity

Similar to stroke in the general population, age is a non-modifiable risk factor. Studies have shown that, in patients who underwent colorectal, joint replacement and lung resection operations, perioperative stroke risk was increased in those beyond the age of 65 years old [4]. In our cohort, the median age of perioperative stroke cases was 69.9 years old [10]. Besides being an independent risk factor, age is associated with other cerebrovascular risk factors, such as hypertension, diabetes mellitus, atherosclerosis and atrial fibrillation.

Hypertension has been shown to associate with stroke in perioperative period. The incident rate of stroke was 0.9% among hypertensive patients as compared with 0.27% among normotensive patients, which represents a three- to four-fold increase in risk [25].

Vascular disease is also a risk factor for perioperative stroke. Peripheral vascular disease has been repeatedly demonstrated as a predictor of perioperative stroke (the role of cerebrovascular disease will be discussed in a later section of this chapter). In a study of post-operative ischemic stroke, the odd ratio for presence of peripheral vascular disease was 5.35

as compared with controls [14]. Peripheral vasculopathy is probably a reflection of the underlying diffuse atherosclerosis that involves the cerebral and cervical vasculatures as well.

Interestingly, chronic obstructive pulmonary disease has also been identified as a risk factor [14]. The odd ratio of perioperative ischemic stroke in patients with chronic obstructive pulmonary disease was report to be 8.77 as compared with control. One may argue obstructive lung disease is more common among elderlies and hence is associated with the risk factor of age. On the other hand, poor respiratory function has been related to increased stroke risk in the general population [26, 27]. It is speculated that hypoxemia secondary to chronic pulmonary disease may aggregate cerebral ischemia.

History of Stroke

History of stroke had been consistently demonstrated to be a risk factor in perioperative stroke. In a 10-year study conducted by Mayo clinic, Rochester, a history of previous cerebrovascular disease was shown to significantly contribute to perioperative stroke risk [14], although the time interval between patient's previous stroke and current surgery did not predict this risk. This increase of perioperative stroke risk is not surprising since this group of patients likely harbor various cerebrovascular risk factors [28]. Also, secondary prophylaxis treatments for stroke such as anti-platelet and anti-coagulation agents have to be withheld during the perioperative period. It is interesting to note that the pathogenic mechanisms of recurrent strokes in the perioperative period are often different from previous episodes. This is different from the findings in the Framingham study which suggested that recurrent stroke is likely caused by the same mechanism of previous strokes [1].

Patients with stroke or transient ischemic attack are advised not to have elective surgical procedures until up to 3 months after the initial event [1, 29]. The rationale underlying this recommendation is to allow the cerebrovascular autoregulation to recover and inflammatory response to wear off. A study has shown that the cerebral autoregulation system would be impaired after stroke not only in the affected side of cerebral hemisphere but also the unaffected side [30]. Acute stroke may impair the baroreflex and vasomotor control and hence induce a labile systemic blood pressure compromising the cerebral autoregulation. This susceptible stage may last a relative long time from days to weeks to recover. For urgent operation, blood pressure has to be carefully monitored and controlled to avoid rapid fluctuations. After the acute phase, the duration between stroke and subsequent surgical operations seems not to have any bearings on the risk of recurrent stroke during the perioperative period.

Carotid Stenosis

Carotid stenosis can be symptomatic or asymptomatic, depending on whether ipsilateral transient ischemic attack or ischemic stroke has occurred. Stroke risk stratification also depends the kind of operation patient is going to receive. Large-scale randomized clinical trial has demonstrated that carotid endarterectomy can benefit patients with symptomatic carotid stenosis of 70 to 99%, provided the operative risk is below 6% and patient's life expectancy is greater than five years [31]. Patients with asymptomatic carotid disease of 60 to 99% can also be benefited from surgery [32, 33]. However, the results of these studies may not be directly applicable to surgical candidates. These studies have commonly excluded patients with co-morbidities such as valvular heart disease, recent ischemic cardiac events, cardiac arrhythmia and organ failures which are frequently encountered among surgical patients.

It is not uncommon for clinicians to pick up asymptomatic carotid bruit as an incidental finding at pre-operative assessment. However, this clinical sign might not be reliable as only around 50% of carotid bruits in asymptomatic patients have hemodynamically significant carotid stenosis [34, 35]. Even if ultrasound screening for carotid stenosis is used, evidence for an association between the degree of stenosis and perioperative stroke is still lacking. Evans and Wijdicks have studied the risk associated with carotid stenosis in 284 patients undergoing general surgery [36]. Carotid stenosis was diagnosed by ultrasound Doppler in 224 patients, and perioperative stroke occurred in 3.6% of them. Interestingly, the degree of stenosis did not correlate with the risk of cerebrovascular complications. Although the incidence of stroke in cohort was higher than unselected populations, the investigators concluded that there was insufficient evidence to support routine carotid stenosis screening and prophylactic endarterectomy.

Another study has shown that intraoperative transcranial Doppler did not reveal significant changes in cerebral blood flow in patients with carotid stenosis [37]. The risk of perioperative stroke among coronary artery bypass graft (CABG) patients with asymptomatic moderate to severe carotid disease (defined as 50 to 99% stenosis) was 3% for unilateral and 5% for bilateral disease, compared to an overall stroke risk of 2%.

For symptomatic carotid stenosis, revascularization may benefit patients undergoing cardiac or major vascular surgery. There is still no consensus on how to manage carotid stenosis among surgical patients. Most debates are in the field of CABG. Recommended strategies include staged carotid endarterectomy before or after coronary bypass, or combined approach in which both operations are performed at the same time [38]. The carotid endarterectomy before CABG approach would increase the risk of myocardial infarction. Conversely, if CABG is performed first, the risk of perioperative stroke would be higher. The American Academy of Neurology concluded that perioperative complication rates were probably similar with combined approach when compared with carotid endarterectomy before coronary artery bypass [39].

In conclusion, there is no standard protocol in screening and managing carotid stenosis in surgical patients. The extent of preoperative investigation and indication of revascularization depends on the degree of stenosis, whether it is symptomatic or not and the nature of foregoing surgical procedure. Clinicians should take a detailed history and neurological examination, aiming to elicit symptoms of subclinical cerebrovascular events. The aim of neuroimaging studies is to look for ipsilateral silent infarct. Further investigations, including transcranial Doppler ultrasonography and computed tomography or magnetic resonance angiography, are other options to provide further information to identify patients who could benefit from prophylactic carotid revascularization.

2) Surgery Factors

Blood Pressure Control

Although hypotension does not appear to be the main cause of perioperative stroke, maintaining a stable blood pressure probably has a role in preventing surgical complications including stroke. As cerebral circulatory autoregulation has its own limitations, if the systemic blood pressure falls below the lower threshold, hypoperfusion to brain tissue occurs, leading to ischemic stroke, especially infarction in the watershed areas. Decrease in cerebral

blood flow may also accentuate ischemic injury resulted from vascular occlusion due to emboli [40]. Maintaining a higher mean blood pressure is associated with decrease in stroke risk associated with CABG [41]. However, the definition of optimal blood pressure level is still debatable. Individualized blood pressure adjustment with reference to preoperative blood pressure may be a logical approach. However, for CABG patients, this customized approach might not be better than using a predetermined arbitrary higher level of mean arterial pressure [42]. The explanation possibly lies on the diffuse atherosclerotic arterial system has reset the lower limit of the autoregulation among patients requiring coronary bypass. Maintaining a higher mean arterial pressure can in general easily overcome the lower threshold of the autoregulation. Further evidence is needed to decide whether the same measure can be applied to non-cardiac surgery.

Anesthesia

Different anesthetic agents and techniques can have different effects on the central nervous system and physiological homeostasis, especially the haemodynamics. Hence the choice of anesthesia may affect the perioperative stroke risk. Local or regional anesthesia when comparing with general anesthesia apparently associates with less systemic disturbance and hence may help to prevent perioperative stroke. In carotid endarterectomy, which both regional and general anesthesia techniques are feasible, the choice of regional anesthesia seems to lower the stroke risk. In a systemic literature review of trials comparing regional versus general anesthesia, it was found that regional anesthesia was associated with 50% reductions in the relative odds of any stroke and or death within 30 days of carotid surgery compared with general anesthesia [43]. In hip fracture repair, there is evidence to show that regional anesthesia results in less blood loss [44]. This may help to prevent stroke complication. Whether it can be generalized to other types of surgical procedure is not yet settled until further evidence is available.

Whether the hypotension induced by general anesthesia is an independent risk factor for perioperative stroke is arguable. Some investigators have found that the hypotensive stage after general anesthesia does not result in elevated stroke risk even in patients with carotid stenosis [37, 45]. The hypotensive effect may be offset by the decrease in cerebral metabolic rate and oxygen consumption due to the anesthetics. But on the other hand, cerebral blood flow to ischemic brain tissue may be reduced by general anesthesia in animal and human models. It has been described as “steal” phenomenon due to presumable vasodilation in non-ischemic areas [46]. Autoregulation impairment and hypocarbia secondary to mechanical ventilation under general anesthesia may contribute to the risk of cerebral infarction [12].

Besides the haemodynamics effect, anesthetics also have pharmacological effects on nervous tissues. The neuroprotective role of anesthetics has been studied in ischemic stroke models. For example, propofol has been shown to protect neuronal cells through various molecular cellular mechanisms [47]. Propofol also has antioxidant activity. It may attenuate neuronal injury by suppressing free radicals in reperfusion of ischemic neuronal tissues. Other anesthetics agents, such as thiopental and etomidate have neuroprotective effect by various mechanisms including decreasing the cerebral metabolic rate and oxygen consumption. Inhalational anesthetics may also play a protective role in cerebral ischemia. Short-duration halothane has been demonstrated to decrease cerebral infarction volume in an animal stroke model when compared with propofol. This protective effect did not mediate through the change in cerebral blood flow [48]. Whether these proclaimed anesthetic neuroprotective

effects which were mainly demonstrated in cell or animal models, can produce observable clinical benefit in perioperative stroke patients is a subject of further clinical studies [49].

Cardiac Surgery

Cardiac surgery can lead to various neurological complications besides stroke. A prospective study designed to study neurological complications in CABG has included 2108 patients [50]. The study found that the complications could be focal injury such as stroke or global injury such as stupor and coma or less well defined neurological outcomes such as deteriorated intellectual functions, memory deficits, or seizures. There were 129 patients, 6.1%, had adverse cerebral outcomes. These patients had relatively longer hospital stay, higher in-hospital mortality and higher rate of institutionalization.

There are issues concerning stroke after cardiac surgery that are worth discussing. First of all, the complexity of cardiac surgery is closely related to the risk of perioperative stroke. For isolated CABG the risk is up to 3.8% [8, 9]; isolated valve surgery the risk is 4.8-8.8% [8]; combined CABG and valve surgery the risk increases to 7.4% [8, 9]; for double- or triple-valve surgery the risk is 9.7% [8]. The increased risk with complexity can probably be explained by longer cardiopulmonary bypass time and operational time, more manipulation of the heart and vascular structures and greater risk of other cardiac complication such as atrial fibrillation or myocardial infarction and hence high risk of perioperative cardioembolism.

Second is that whether the off-pump surgery can reduce the perioperative stroke risk is still controversial. Extracorporeal circulatory pump system used for cardiopulmonary bypass can be a source of embolism in the pathogenesis of perioperative stroke. When blood is circulated through the system, microemboli can form over the internal surface of the extracorporeal bypass pump and its tubing, despite heparin is used [51]. Intense inflammatory response can be triggered when blood flows through the artificial system. During the bypass, the pulmonary circulation is skipped which normally functions as a filter for any microembolus flowing from the venous to the arterial system. Non-pulsatile blood flow may also favor the formation of emboli. Also, aortic instrumentation and manipulation, including cannulation, decannulation, clamping and unclamping, can result in disruption of atherosclerotic plaques in the aorta leading to cerebral embolism.

Transcranial Doppler ultrasound study has demonstrated that the off-pump operations had relatively low emboli load when compared with on-pump procedures. However, studies have shown inconclusive results in correlating off-pump surgery and stroke risk. In a meta-analysis by Wijeyesundera et al. [51], including 37 randomized control trials with 3,449 subjects, off-pump surgery showed a reduction in stroke complication but it did not reach a statistical significance (odd ratio 0.52; 95% confidence interval 0.25 to 1.05). The meta-analysis also included 22 observational studies, including 293,617 subjects. These observational studies concluded that off-pump surgery could prevent perioperative stroke (odd ratio 0.62; 95% confidence interval 0.55 to 0.69). In another large meta-analysis including 37 randomized control trials with 3,396 subjects [52], there was no statistical significant reduction in perioperative stroke with off-pump surgery (odd ratio, 0.68; 95% confidence interval, 0.33–1.40), although this study might have considerable overlapping with Wijeyesundera's study in recruiting trials for meta-analysis. Biancari et al. has reported that the off-pump coronary artery bypass surgery could prevent perioperative stroke among patients with high stroke complication risk and when intraoperative epiaortic ultrasound scanning was used [53]. The high risk group was defined by the Northern New England Cardiovascular Disease Study

Group (NNECVDSG) stroke risk score. The NNECVDSG stroke risk score is a tool for stratifying perioperative stroke risk among CABG patients and its details will be discussed further later in this chapter.

Besides developing the off-pump technique, efforts have been paid to improve the cardiopulmonary bypass system. The mini-extracorporeal circulation (MECC), is an example. It is a cardiopulmonary bypass circuit that requires a relatively small prime for the centrifugal pump. It can minimize blood-air contact as it needs neither an open venous reservoir nor direct reinfusion of cardiectomy suction from the pericardial space. It is considered to limit the systemic inflammatory response when blood flows through the system.

In a prospective randomized study, 300 patients were assigned to either MECC or conventional on-pump CABG [54]. No difference was found between the two groups in operative mortality and morbidity, transfusion rates, hospital stay, and inflammatory markers. In a smaller randomized study, 40 patients were assigned either to MECC or conventional on-pump operation [55]. The MECC was shown to have better outcomes, though the perioperative stroke risk was not specifically studied.

Third issue worth paying attention is the surgical technique in cardiac surgery. Surgery involving the manipulation of the aorta carries the risk of embolic stroke due to disruption of the aortic atherosclerotic plaques. McKhann et al. has shared the experience in reducing stroke complication of cardiac operation by adopting 'single clamp technique' [9]. Instead of the conventional 'double clamping technique' by applying two clamps, that is one aortic clamp and a side biting clamp, over the aorta, the 'single clamp technique' minimized the aorta manipulation by applying one clamp only. Use of the intra-aortic filter to capture the emboli is another feasible approach. It has been shown in prospective study that the use of aortic filter resulted in better neurological outcomes in the high risk group [56].

On the other hand, the use of epiaortic or transesophageal ultrasonography can help to identify atherosclerotic plaques in the aorta. Surgeons can decide their operational approach in view of the location and morphology of the aortic plaque [53]. Flat atherosclerotic lesions over the posterior wall of ascending aorta or at the origin of the brachiocephalic trunk are considered safe for side bite clamping as they are far from the clamping site. Unstable plaque such as the exophytic lesions are a contraindication to aortic manipulation. The ultrasonography can also assess the presence of patent foramen ovale, left ventricular or atrial thrombi which all can predispose to perioperative stroke.

PERIOPERATIVE DRUG USE

Anti-platelet Agents or Anti-coagulants

Neurologists are often consulted when to withhold the anti-platelet or anti-coagulation agents before surgery. It depends on the indication of agents and the bleeding risks of the procedure. The American College of Chest Physicians has issued guidelines on perioperative anticoagulants adjustment [57]. For patients with significant risk, such as those with prosthetic heart valves, recent cerebrovascular events and atrial fibrillation with other cerebrovascular risk factors, bridging heparin therapy is recommended while withholding oral anti-coagulation. The dosage of heparin has to be carefully administrated and the neurological

status should be closely monitored as one study has shown increased risk of perioperative hemorrhagic stroke especially in those with previous stroke [1]. On the other hand, withholding these agents may lead to rebound hypercoagulation in the postoperative prothrombotic stage.

Statins

Statins or HMG-CoA reductase inhibitors have been proposed to reduce perioperative stroke risk. Besides their lipid lowering action, these agents offer other vascular protective functions, including improvement in endothelial function, atherosclerotic plaque stabilization and decrease of inflammatory markers, the so called pleiotropic effects [58]. Statins can suppress the level of isoprenoids, which are the intermediates in cholesterol metabolism. Various cytokines and inflammatory mechanisms are attenuated by reduction in isoprenoids which plays an important role in triggering signaling pathway leadings to inflammatory cascade [58].

Surgical candidates are advised to take statins around 4 weeks before surgery, irrespective of their lipid levels. The patients with cardiovascular diseases are advised to continue the statin after the surgery as long as it is not contraindicated [58]. But there is no consensus in the drug duration in patients without cardiovascular disease. Long acting formula drugs are preferred [59].

In a large-scale meta-analysis involving over 30,000 patients, statin has been demonstrated to reduce perioperative stroke in patients undergoing cardiac surgery [60]. However, in a Cochrane review, statin use was not related to lower perioperative stroke risk in mainly cardiac revascularization recipients. The review included 11 randomized controlled studies with 984 subjects undergoing on- or off-pump cardiac operations. Statin pre-treatment before surgery reduced the incidence of post-operative atrial fibrillation, was associated with a shorter length of stay in the intensive care unit and in the hospital but failed to prevent post-operative stroke [61]. In a study on the effects of statin use on perioperative hemodynamic parameters and its clinical outcome in on-pump coronary bypass grafting or valvular surgery, the authors concluded that the treatment did not affect the hemodynamics and the surgical outcome [62]. The discrepancies in the results probably lie on the selection of studies in different meta-analyses. The controversies will likely go on until more randomized controlled trials are conducted.

Beta-Blockers

Beta-blockers were once recommended for patients preparing to have vascular surgery and patients with high risk for coronary disease preparing to have intermediate to high risk non-vascular surgery. Some studies suggested beta-blockers could prevent perioperative atrial fibrillation [63]. However, the landmark POISE trial has shown perioperative use of metoprolol was associated with a 30% decrease in non-fatal myocardial infarction but also a 117% increase in stroke [64]. In a meta-analysis included over 12, 000 patients, beta-blockers were shown to increase stroke risk, with odd ratio of around 2 [65]. The rationale was

supposed to be the induced hypotension. But since hypotension is not the main cause of perioperative stroke, there may be other mechanisms for this association yet to be discovered.

Risk Stratification

Various perioperative stroke risk-predicting models have been developed to stratify the risks among surgical candidates. McKhann et al. used three factors to predict stroke risk among patients undergoing CABG, including age, previous stroke history and hypertension. The model returns a relative probability of perioperative stroke [9]. The Northern New England Cardiovascular Disease Study Group (NNECVDSG) has proposed another model in predicting stroke risk in CABG patients [66]. The model was based on an observational study of over 33,000 consecutive CABG patients [67]. It was a scoring system consists of seven items including age, emergency of the surgery, gender of the patient, cardiac ejection fraction, serum creatinine level, presence of valvular disease and diabetes mellitus. Each item had different weighted score. Estimated stroke risk could be obtained by matching the total score from a table.

In a recent study, a model has been established trying to predict the perioperative stroke risk in non-cardiac and non-neurological surgery [20]. The model was based on a prospective study on the risk factors of perioperative stroke. It consisted of 9 identified risk factors and 1 protective factor. The risk factors included age of 62 or above; myocardial infarction within 6 months; acute renal failure; history of stroke; pre-existing dialysis; hypertension; history of transient ischemic attack; chronic obstructive pulmonary disease; and current smoking habit. High body mass index in the range of 35 to 40 kg/m² was considered as a protective factor. This contradicts to the common believe that obesity is a risk factor of cerebrovascular disease. The authors defended that higher BMI might protect against stroke-associated mortality in the elderly but not the young stroke patients. The predicting model classified the surgical candidates into 3 groups with low, medium and high risks. The odd ratios of perioperative stroke could be calculated by the statistical model used in the prospective study.

Such predictive models can help to provide feasible means for clinicians to assess the perioperative stroke risk, though the reliability have to be further confirmed. Also, whether similar models can be established for different types of operation is subjected to further studies.

Treatment

Although most cases of the perioperative ischemic stroke occur in in-patient setting, intravenous thrombolytics cannot be given due to recent surgical operation despite the diagnosis can probably be made within therapeutic windows. Intra-arterial thrombolysis is theoretically feasible option, though there is still no large scale trial to prove its efficacy and safety in perioperative stroke. In a retrospective case series, the intra-arterial thrombolytic use within 2 weeks of postoperative period achieved recanalization rate of 39% and Rankin score less than or equal to 2 at 1 week post-therapy in 38% of the patients [68]. The therapy carried 25% of bleeding risk but most were minor bleeding at surgical wound. Most of the cases with major surgical site bleeding were intracranial surgery patients. So the therapy was suggested

to be avoided in this group of patients. Whether the mechanical clot retrieval therapy can achieve the therapeutic goal with avoidance of the complication of bleeding, further studies are needed.

CONCLUSION

Perioperative stroke is an uncommon but severe surgical complication. It is associated with high mortality. Cardiac and vascular operations have the greatest risks. Embolism is a major pathogenic mechanism of perioperative stroke. Although hypotension is not a major culprit, maintaining a static blood pressure during and after the operation may probably help to prevent the complication. Anesthesia technique and anesthetics choice may modify the susceptibility or the damage due to stroke in perioperative period. Patients taking antiplatelets or anticoagulants should be managed according to bleeding risk of the procedure and the indication of the medications. Betablockers tends to increase the stroke risk due to unknown mechanism. Statins probably protect patients from stroke by the pleiotropic effects. Various investigators have developed different models to predict the perioperative stroke risk. But these are mainly in the field of cardiovascular surgery. More attention should be paid in the non-cardiac surgery. Treatment is mainly based on experience of individual institute as there is no established guideline and the expertise required may not be available in every center.

Chapter 9

TRADITIONAL MEDICINE IN THE TREATMENT AND PREVENTION OF ISCHEMIC STROKE

Amy C. Y. Lo and Di Yang*

Eye Institute, The University of Hong Kong

ABSTRACT

Ischemic stroke is a leading cause of death worldwide, bringing about serious long lasting disability and considerable social burden. During ischemic stroke, ischemia takes place due to blood flow interruption as a result of cerebral artery blockage and subsequently reperfusion occurs, triggering a complex cascade of molecular events that eventually results in irreversible cell death, affecting functioning of the brain and body. Sometimes vision impairment also occurs due to ischemia/reperfusion injury in the retina. Treatment of ischemic stroke is important to alleviate the subsequent outcome. Yet, no ideal neuroprotective agents are available. Some research has turned to traditional medicine, which has been used for decades. The traditional medicine has shown efficacy in cell and animal models, making it an attractive option in treatment of ischemic stroke. Another attractive alternative would be the prevention of ischemic stroke using traditional medicine, which may be beneficial for patients at high risk for ischemic stroke. This chapter aims to give an overview of the traditional medicine being tested and its efficacy in the treatment and prevention of ischemic stroke.

ABBREVIATIONS USED

Ach	acetylcholine
AMPA	2-amino-3-(5-methyl-3-oxo-1,2-oxazol-4-yl)propanoic acid
BDNF	brain-derived neurotrophic factor
BNJ	Buchang Naoxintong Jiaonang
BrdU	5-bromodeoxyuridine

BYHWD	Buyang Huanwu decoction
CAT	catalase
COX-2	cyclooxygenase-2
DJ	Danqi Piantang Jiaonang (DJ)
DPPH	1,1-diphenyl-2-picrylhydrazyl
FDA	Food and Drug Administration
GABA	γ -aminobutyric acid
GDNF	glial cell line-derived neurotrophic factor
GFAP	glial fibrillary acidic protein
GPx	glutathione peroxidase
H ₂ O ₂	hydrogen peroxide
HHD	Huang Lian Jie Du decoction
HIF-1 α	hypoxia-inducible factor-1 β
hsp70	heat shock protein 70
ICAM-1	Intercellular Adhesion Molecule 1
IL-1 β	interleukin-1 β
IL-6	interlukin-6
iNOS	inducible nitric oxide synthase
I/R	ischemia/reperfusion
KFW	Kueichih Fuling Wan
LBP	extracts of <i>L. barbarum</i> containing mostly polysaccharides
LDH	lactate dehydrogenase
LDL	low density lipoprotein
LPS	lipopolysaccharides
LTP	long term potentiation
MCAO	middle cerebral artery occlusion
MDA	malondialdehyde
MMP	mitochondrial membrane potential
MPO	myeloperoxidase
NaCN	sodium cyanide
NINDS	National Institute of Neurological Disorders and S troke
NMDA	N-methyl-D- aspartate
nNOS	neuronal nitric oxide synthase
NO	nitric oxide
PAF	platelet-activating factor
OGD	oxygen-glucose deprivation
NF- κ B	nuclear factor kappa-light-chain-enhancer of activated B cells
QKL	Qingkailing
QZT	Qizhu Tang
rCBF	regional cerebral blood flow
ROS	reactive oxygen species
RQKL	Refined Qing Kai Ling
rtPA	recombinant tissue plasminogen activator
SMS	Shengmai San
SOD	superoxide dismutase

TAM	Traditional African medicine
TCM	traditional Chinese medicine
TCPM	traditional Chinese patent medicine
TBARS	thiobarbituric acid reactive substances
TEM	Traditional Eastern medicine
TMP	2,3,5,6- Tetramethylpyrazine
TNF α	tumor necrosis factor α
VEGF	vascular endothelial growth factor
WHO	World Health Organization

INTRODUCTION

Stroke is a devastating cerebrovascular disease and the second leading cause of death throughout the world. Each year, more than 15 million people suffer from stroke and one-third of them die. The rest of the survivors might be left with various cruel sequelae, including hemiplegia, dysesthesia, ataxia and even visual impairment. Management of these subsequent disabilities poses an increasing burden to the whole society as the population ages. There are two major categories of stroke according to its etiology, namely ischemic stroke and hemorrhagic stroke. Of them, ischemic stroke accounts for approximately 80% of total cases [1]. During ischemic stroke, ischemia takes place due to blood flow interruption as a result of cerebral artery blockage and subsequently reperfusion occurs, triggering a complex cascade of molecular events that eventually results in irreversible cell death, affecting functioning of the brain and body. This cell death, induced by ischemia/reperfusion injury, is a complex interaction of multiple events involving apoptosis, oxidative stress and inflammation [2].

Present management for acute ischemic stroke mainly focuses on early re-vascularization including pharmacologic thrombolysis, mechanical thrombectomy and angioplasty. The key therapeutic strategy of the management is to restore the blood flow to ischemic brain tissue at an early stage in order to protect the neurons from further damage and reduce the long-term disabilities associated with stroke attack. To date, the only approved medicine for acute ischemic stroke by the Food and Drug Administration (FDA) is recombinant tissue plasminogen activator (rtPA). Approval was granted after a large, randomized, placebo-controlled study by the National Institute of Neurological Disorders and Stroke (NINDS) that showed a significant improvement in 3-month outcomes with rtPA [3]. In a 12-month follow-up study, patients with acute ischemic stroke who were treated with rtPA within 3 hours after symptom onset were at least 30% more likely to have minimal or no disability than placebo-treated patients at 12 months [4]. Despite the wide acceptance of rtPA in ischemic stroke treatment, there still remains controversy since it increases the risk of symptomatic intracranial hemorrhage [3-5]. In this case, rtPA is only recommended for carefully selected patients who are eligible according to the treatment criteria. The restrictive 3-hour time window necessary for the use of rtPA further limits the number of patients who will receive the intervention. It is estimated that only about 1-2% of patients with acute ischemic stroke have received this intervention [6].

Due to the narrow time window and adverse effects after ischemic stroke such as hemorrhagic transformation, ischemia/reperfusion damage and re-occlusion after recanalization, neuroscientists have become more emphasized on neuroprotection in the treatment of ischemic stroke. Physicians and neurologists have attempted to approach stroke patients with combining neuroprotective agents to salvage cell death. Currently the most studied neuroprotective agents include glutamate receptor antagonists, ion channel modulators, anti-inflammatory agents, and free radical scavengers [7]; simply speaking, in almost all components of the ischemia cascade. Despite the determined efforts in basic research and clinical investigation, neuroprotective therapies for acute ischemic stroke remain unsuccessful. They all appear to be effective in initial studies using a variety of animal stroke models; however, the outcomes of the subsequent clinical trials are far less from satisfactory. None of them have been proven effective in clinical practice [5].

With an increasing population of elderly people worldwide, stroke has become a major healthcare problem. Although the incidence of stroke has been reduced by preventive measures such as controlling hypertension, hypercholesterolemia and smoking, there remains an urgent need for effective and widely applicable pharmacological treatment. This lack of treatment for stroke may explain the growing attention in traditional medicine in the last few decades, in which abundant clinical data as well as extensive observational and anecdotal experiences have accumulated over the past millenniums.

Chinese herbal medicine has been used to treat ischemic stroke for ages. Although its efficacy has been corroborated by the outcomes of patients, the underlying mechanisms and specific active ingredients still remains unknown. Dozens of Chinese herbs, either crude or extract, have been tested in various pre-clinical animal studies and clinical trials.

This article reviews their distinct abilities in both prevention and treatment of ischemic stroke.

TRADITIONAL MEDICINE – AN OVERVIEW

In 2003, the World Health Organization (WHO) defined traditional medicine as “health practices, approaches, knowledge and beliefs incorporating plant-, animal- and mineral-based medicines, spiritual therapies, manual techniques and exercises, applied singularly or in combination to treat, diagnose and prevent illnesses or maintain well-being” [8].

Traditional medicine, also termed as complementary or alternative medicine, arises in ancient times before the establishment of modern Western medicine and is developed in various regions around the world over generations. Traditional African medicine (TAM) and Traditional Eastern medicine (TEM) are the two major branches. Indeed, traditional medicine has been used in African and Asian communities for thousands of years, and shows increasing popularity in Western society. According to WHO’s statistics and investigations, there are approximately 80% of the population who depends on traditional medicine for primary healthcare in some African and Asian countries, while in many developed regions, such as Europe and North America, 70% to 80% of the population has at least once being treated by traditional medicine [9].

Traditional African Medicine (TAM)

The pivotal theoretical concept of TAM relies on the belief in the supernatural [10], in which serious illness can be underpinned e.g., by ancestor spirit anger [11, 12]. TAM practitioners usually use divination as a diagnostic process [13] and treat the disease with ritualized use of plant- or animal-derived preparations. Plant remedies are commonly used for dealing with minor illnesses such as fever, aches and pains [14, 15] without recourse to spiritual evocations in most African communities. For more persistent illnesses or when the illness becomes life-threatening, a specialist is consulted and divination is used.

Studies have now revealed that there are many useful molecules in the plant preparations with anti-inflammatory properties. These include salicin from willow (*Salix alba*), quinine from cinchona (*Cinchona succirubra*), artemisin from quin hao (*Artemisia annua*), and gedunin from *Azadirachta indica* [15-17]. However, there seemed to be scarce reported investigations about plant remedies in TAM in treating stroke. In addition, the lack of scientific explanation of TAM has restricted its intensive study and development.

Traditional Chinese Medicine (TCM)

Apart from the African society, traditional medicine has been mostly accepted in the eastern countries, such as China, Japan and Korea. The use of traditional medicine in China, also known as traditional Chinese medicine (TCM), is very prevalent due to not only its long history but also its recognized efficacy. TCM is a precious heritage of China. Its usage, safety and effectiveness have accumulated over thousands of years and are verified by the long-term practice in the Chinese population. Its practical value is unquestionable; yet, its success would only be more convincing if the effectiveness can be explained by modern scientific theories and methodologies. The vast experience with TCM in human provides a strong basis for modern basic pharmacological research.

STROKE

Cerebral Ischemia – Pathophysiology and Mechanisms

The pathophysiology of cerebral ischemia has been well covered by many stroke researchers [2, 18]. In ischemic stroke, complex spatial and temporal events evolve over hours or even days.

Cerebral ischemia occurs as a result of an obstruction in one of the major cerebral blood vessels, resulting in reduced blood supply and therefore insufficient glucose and oxygen delivery to affected areas in the brain. An ischemic core and the penumbra surrounding it are developed [19, 20]. As appropriate blood supply is essential to maintain proper neuronal function in the nervous system, neuronal activity declines rapidly when the blood flow drops below 25% of normal values. Within the core of the ischemic territory where blood flow is most severely restricted, cellular homeostasis could not be supported and severe impairment of ATP-dependent cellular activities occurs, leading to excitotoxic and necrotic cell death [21,

22]. Not only are the neurons affected, other cells such as glia and endothelial cells are also damaged.

Ischemic stroke triggers a complex cascade of cellular and molecular events associated with ischemia/reperfusion (I/R) injury. The cascade begins with energy depletion, disruption of ion homeostasis, depolarization, calcium channel dysfunction, excessive glutamate release, excitotoxicity, and release of free radical that rapidly result in cell death in the infarct core. These early events are followed by late events such as inflammatory changes, apoptosis and disruption of the blood-brain barrier [23].

Yin-Yang Theory in TCM

The underlying principles of TCM are very different from Western medicine. Theoretically, various doctrines such as ‘Yin-Yang’, ‘Five Elements’, five ‘Zang’ and six ‘Fu’ viscera, and ‘Meridians’ (channels and collaterals) are involved [24]. In the Yin-Yang theory, ‘Yin’ and ‘Yang’ are two opposing but complementary forces of energy. They govern the essential organs in our human body, especially heart, lungs, liver, kidneys, and spleen. It is believed that diseases originate from the imbalance between ‘Yin’ and ‘Yang’. For TCM practitioners, treatment is based on this theory and they use different approaches to restore the balance between ‘Yin’ and ‘Yang’.

Basic Principles of Stroke in TCM

In TCM, stroke is a syndrome known as ‘wind stroke’. It is characterized by a sudden appearance of facial paralysis, impeded speech and/or hemiplegia. Five pathogenic factors are involved: ‘external wind’, ‘internal liver wind’, ‘phlegm’, ‘fire’, and ‘stagnation’.

These five factors can interact with each other, which, in turn, may lead to ‘Yin’ or ‘Qi’ (internal strength) weakness, ‘liver fire’, ‘wind phlegm’, ‘phlegm dampness’, or ‘blood stasis’ [25]. This results in imbalance between Yin and Yang, disturbance of the blood and ‘Qi’ circulation, deficiency of ‘liver-Yin’ and ‘kidney-Yin’, stagnation of phlegm and dampness, and eventually sudden onset of wind stroke [25].

TRADITIONAL CHINESE MEDICINE AND STROKE THERAPY

In TCM, the treatment of stroke aims to restore the equilibrium of the relative strength between the patient’s body resistance and the intensity of endogenous and exogenous pathogenic factors [25, 26]. According to the cause of wind stroke, different TCM treatments are given. These include heat-clearing drugs, anti-rheumatics, drugs for promoting blood circulation, drugs for dispersing external wind, drugs for relieving phlegm, drugs for subduing interior wind, drugs for resuscitation, and tonics for deficiency syndromes [25, 27].

Some of the actions of TCM in stroke therapy can be explained based on the pathophysiology of cerebral ischemia. They contain agents with anti-oxidative, anti-inflammatory and anti-thrombotic properties. For example, many herbs contain flavonoids,

whose anti-oxidative activity has been shown *in vitro* [28]. Flavonoids are also shown to have anti-inflammatory activities [29, 30], which may be desirable in stroke treatment. In addition, some herbs can dilate blood vessels and suppress platelet aggregation [31].

Herbal medicine, prescriptions, acupuncture, massage, and dietary therapy constitute the various forms of TCM treatment. Among them all, the usage of herbs, prescriptions and acupuncture are intensively investigated in the prevention and treatment of stroke.

Herbs Used for Treatment or Prevention of Stroke in TCM

There are more than 100 herbs that have been used in stroke prevention or treatment. Some of their active ingredients have been described in detail [25, 27, 32]. Examples of the more commonly used herbs are discussed below in alphabetical order. The active components in these herbs and their mechanisms of action in relation to cerebral ischemia pathophysiology stroke are also described.

Acanthopanax Senticosus Harms

The stem bark of *Acanthopanax senticosus* Harms (*Eleutherococcus senticosus* Maxim, *Araliaceae*) is very often called Siberian Ginseng. It is used to strengthen 'Qi' in TCM [33]. It has also been used as a tonic for chronic bronchitis, hypertension, ischemic heart disease, and anti-stress [34]. Siberian Ginseng exhibits effects such as anti-fatigue, anti-stress, immuno-enhancing, and anti-depressive effect [35]. It is also shown to be hepato-protective through its antioxidant activities [36, 37].

From the stem bark, many phenolic compounds including lignan glycosides (the glycosides of pinoresinol, medioresinol and syringaresinol), isofraxidin, isofraxidin 7-O-glucoside, chlorogenic acid, 2,6-dimethoxy-p-benzoquinone and syringin have been isolated [38]. Another component, liriodendrin, is also isolated and has been demonstrated to have anti-inflammatory effects. It significantly inhibits the increase of vascular permeability induced by acetic acid in mice and reduces the acute paw edema induced by carrageenan in rats [34]. On the other hand, the saponins isolated from the leaves can reduce the size of acute myocardial infarcts in dogs [39].

Angelica Sinensis, A. Gigas

Angelica sinensis is used in China while *Angelica gigas* is used in Korea [27]. The dried root of *A. sinensis*, also known as *Radix angelica sinensis*, is commonly used as a treatment regimen for anemia or some circulatory disorders [40]. It has also been used to treat menstruation and menopause syndrome in women [27].

A. sinensis root extracts ameliorate scopolamine- and cycloheximide-induced amnesia, but not p-chloroamphetamine-induced amnesia in rats [41]. *Radix angelica sinensis* is shown to display free radical scavenging properties [42]. Moreover, *Radix angelica sinensis* can dose- and time-dependently protect human umbilical vein endothelial cells (ECV304) against hydrogen peroxide damage and suppress the production of reactive oxygen species (ROS) [43].

Several active components have been identified in *Radix angelica sinensis*. They are ferulic acid, ligustilide, angelicide, brefeldin A, butylidenephthalide, butyphthalide, succinic

acid, nicotinic acid, uracil, and adenine [27]. Among them, ferulic acid has demonstrated neuroprotective properties. Ferulic acid significantly reduces cerebral infarct and neurological deficit-score in rats after middle cerebral artery occlusion (MCAO), may be by suppressing superoxide radicals in the parenchyma lesion and intercellular adhesion molecule 1 (ICAM-1) immunoreactive vessels in the ischemic striatum as well as reducing the expression of ICAM-1 and nuclear factor kappa-light-chain-enhancer of activated B cells (NF- κ B) in the ischemic cortex and striatum [44].

The crude extract of *A. gigas* roots also displayed anti-nociceptive properties in various pain models [40]. Long-term administration of extract of *A. gigas* root or decursinol exerts protection against β -amyloid peptide-induced memory impairment in mice [45]. Decursin, one component in the root of *Angelica gigas*, mitigates amnesia induced by scopolamine in mice [46].

Astragalus Membranaceus

Astragalus membranaceus is a herbal medicine routinely used in patients with stroke or chronic debilitating diseases in China for decades. Even normal subjects who wish to further improve their vital functions regularly use *A. membranaceus* [47]. A previous pilot study suggested that *A. membranaceus* is safe and may be beneficial in treating acute cerebral infarction [48].

Astragaloside IV is a saponin and the major active constituent of *Astragalus membranaceus*. Previous pharmacological studies showed that Astragaloside IV displays a series of protective effects; these include anti-hypertension [49], anti-inflammation [50], anti-infarction [47], anti-nociception [51], anti-viral activity [52], and positive inotropic action [53]. *In vitro* studies have shown that Astragaloside IV is a strong scavenger for superoxide radicals and hydroxyl radicals [54]. *In vivo* studies also showed that Astragaloside IV is neuroprotective in a number of ischemia models. It reduces infarct volume as well as decreases the levels of malondialdehyde (MDA) and increases the levels of antioxidant enzymes glutathione peroxidase (GPx) and superoxide dismutase (SOD) in ischemic mouse tissue after MCAO-induced I/R injury [47]. In addition, Astragaloside IV protects the blood-brain barrier and reverses the decreased expression of tight junction proteins in a rat model of focal I/R injury [55]. It was further shown in the same model that Astragaloside IV can prevent neutrophil accumulation and suppress neutrophil adhesion-related molecules, thereby exerting neuroprotection against I/R injury [56]. Moreover, Astragaloside IV pre-treatment is shown to be neuroprotective and these effects may be associated with improved cellular energy metabolism, inhibition of JNK pathway activation and then suppression of the mitochondrial apoptosis pathway [57].

Bombycis Corpus

Bombycis corpus is the dried larva of the silk moth *Bombyx mori*, dead as a result of the infection by the fungus *B. bassiana* [27]. It is used to treat symptoms induced by stroke such as convulsion, headache, palsy, and speech problems. *B. corpus* is protective against cytotoxicity induced by A β ₂₅₋₃₅ in cultured astrocytes through the inhibition of lipid peroxidation and protection of anti-oxidative enzymes [58]. Sphingolipids isolated from *B. Corpus* have demonstrated neurotrophic effects in PC12 cell neurite outgrowth [59]. Pre-treatment of *B. corpus* not only reduce the N-methyl-D- aspartate (NMDA)-induced

neurotoxic actions in the hippocampus but also protected cultured neurons against the neurotoxic actions of either 2-amino-3-(5-methyl-3-oxo-1,2-oxazol-4-yl)propanoic acid (AMPA) or kainic acid [60]. Because the release of glutamate has been implicated in cerebral ischemia injury, *B. corpus* may contribute significantly to protect the human brain.

Carthamus Tinctorius

Carthamus tinctorius (Honghua in Chinese) is the flower (or petal) of the Chinese safflower. This material is used in TCM for a wide variety of disorders, but most often for conditions expected to benefit from increased local or visceral blood flow. These include topical application for traumatic wound healing and systemic administration for amenorrhea, coronary heart disease and cerebrovascular disease [61]. In the *ex vivo* chick embryo retina assay, Honghua protects against excitotoxicity caused by glutamate, NMDA, kainate, and quisqualate as well as against neuronal degeneration caused by simulated ischemia. In the *in vivo* adult rat retina, intravitreal injection of Honghua greatly reduces ischemic damage [61]. In rats challenged with MCAO, Honghua extracts exhibit significant neuroprotective effects in decreasing neurological deficit scores and reducing the infarct size [62]. *In vitro* studies in cultured cortical neurons show that Honghua extracts significantly inhibit neuron damage induced by exposure to glutamate and sodium cyanide (NaCN) [62].

Corydalis Yanhusuo

In TCM, the tubers of *Corydalis yanhusuo* are used mainly as an analgesic in the treatment of gastric and duodenal ulcer, rheumatism and dysmenorrhea [27]. The tubers contain pharmacologically active alkaloids that have analgesic [63], anti-inflammatory [64], anti-thrombotic [65], and anti-hypertensive effects [66]. Several active ingredients have been identified. One of them is DL-tetrahydropalmatine, whose pre-treatment provides neuroprotective effect in rats affected by heatstroke [67]. It also protects neurons [68], improves neurological status and reduces the cerebral infarct size [69] in rats after I/R injury. Protopine is another component that has an inhibitory activity on platelet aggregation in rabbits [70].

Ginkgo Biloba

Ginkgo biloba L. is a tree indigenous to China [71]. *Ginkgo biloba* L., its leaves in particular, has a long history of being used for medicinal purposes [72, 73]. *G. biloba* extract has been widely used to treat circulation disorders [74], cerebrovascular insufficiency [75], peripheral vascular disease such as arterial occlusive diseases [76], age-dependent damages [77] and dementia [78]. The mechanism and clinical indications of *G. biloba* extract have been well covered by Diamond et al. [77].

The primary compounds of interest in ginkgo are ginkgolides and flavonoids, which exhibit bioactivity. In a recent HPLC analysis, the quality of *G. biloba* extract has been standardized as containing 22 – 27% w/w flavonoid glycosides and 6% w/w terpenoids [73]. EGb 761 is a standardized extract of *G. biloba* leaves. It contains ~24% flavonoid glycosides (primarily quercetin, rutin, kaempferol and isohamnetin), 6% terpene lactones, 2.8-3.4% ginkgolides A, B and C, and 2.6-3.2% bilobalide [27]. The flavonoids in EGb appear to possess strong free radical scavenging and anti-inflammatory properties [79, 80] while the

terpenoids and ginkgolides A and B inhibit platelet-activating factor (PAF) and decrease free radical release [81, 82].

Treatment with *G. biloba* extract has shown beneficial effects in reducing reperfusion injury in global ischemia and trauma experimental models [83]. *G. biloba* extract reduces infarction volume in mice with MCAO and reperfusion [84, 85]. In particular, EGb 761 reduced the size of cerebral infarction and improved neurological behavior in rats with transient and permanent focal cerebral ischemia, partially attributed to the beneficial effects of selectively improved local cortical blood flow in the area at risk of infarction [86].

G. biloba extract has both a scavenging effect on superoxide anions and an enhancing effect on SOD activities, which prevents oxidative stress in neurons [87, 88]. Free radical scavenging activity was also previously demonstrated in *G. biloba* L. leaves, which is likely to be attributed to the presence of quercetin and rutin that have free radical scavenging activity [89]. EGb 761 also shows anti-oxidative activities [90].

In particular, bilobalide, a constituent of *G. biloba*, demonstrates potent neuroprotective effects. Bilobalide pre-treatment reduces the cerebral infarct size [91]. It also suppresses hypoxia-induced membrane breakdown in the brain [92] and inhibits NMDA-induced phospholipase A2 activation and phospholipid breakdown in rat hippocampal slices [93]. Bilobalide can induce the expression of glial cell line-derived neurotrophic factor (GDNF) and vascular endothelial growth factor (VEGF) in rat astrocytes *in vitro* [94].

Despite the evidence and similar to other TCM herbs, many randomized controlled trials for *G. biloba* extract were of inferior quality [95]. One placebo-controlled trial was assessed to be of good quality, but it failed to show an improvement of neurological deficit at the end of treatment using *G. biloba* extract [95]. There is no convincing evidence to demonstrate the effectiveness of the routine use of *G. biloba* in promoting recovery after stroke. Large-scale randomized controlled trials of high quality are necessary [96].

***Ligusticum Wallichii* Franchat**

Ligusticum wallichii Franchat (Chuan Xiong) has been used for at least 200 years by TCM practitioners [97.] It is commonly used to stimulate blood circulation and relieve pain [97] as well as to treat neurovascular and cardiovascular diseases [98]. 2,3,5,6-Tetramethylpyrazine (TMP) is one of the most important active ingredients isolated from Chuan Xiong [99]. TMP pre-treatment is neuroprotective through the suppression of inflammatory reaction and reduction of neuronal apoptosis in focal cerebral ischemic/reperfusion injury [100]. In addition, TMP protects the gerbil hippocampus against global cerebral ischemia [101] and rat brain against MCAO-induced focal cerebral ischemia [102]. Moreover, in rats with transient focal cerebral I/R injury, administration of TMP within a 4-hour time period post-stroke may reduce cerebral ischemic reperfusion damage [103]. In PC12 cells exposed to oxygen-glucose deprivation (OGD), TMP increases the survival rate of PC12 cells activation of the ActA/Smad signaling pathway and its anti-oxidative activities [104].

Two clinical trials were previously performed to test the efficacy of Chuan Xiong. However, the quality of these trials was low and did not yield any reliable evidence [105]. Similar to other TCM herbs, large-scale randomized controlled trials of good quality are necessary for any clinical recommendation.

Lycium Barbaarum L.

The fruit of *Lycium barbarum* (also named Wolfberry, *Fructus Lycii*, Gouqizi) has been widely used in Chinese herbal recipes for thousands of years. According to traditional Chinese medicine literature, *L. barbarum* can nourish the liver and kidney, helping the re-balance of 'Yin' and 'Yan' in the body. *L. barbarum* is an important ingredient in traditional Chinese medicine in promoting health and longevity. It is also taken as a food supplement in the Western countries.

L. barbarum has an attractive red color, leading to the belief that it has a role in strengthening eyesight and protecting the eyes. Chemical analysis of *L. barbarum* shows that it indeed contains lots of carotene and zeaxanthin, which can provide nutrients and antioxidants directly to the eyes [106]. Yet, carotene is normally not obtained from *L. barbarum* in our daily diet. In *L. barbarum*, the polysaccharides constitute more than 40% of the fruit extract [107]. Numerous experimental studies have revealed that *L. barbarum* has a wide array of functions, which may be due to its high polysaccharide content. These include anti-aging, anti-tumor, cytoprotective, neuromodulation, and immune modulation effects [107]. In addition, pre-treatment using extracts of *L. barbarum* containing mostly polysaccharides (LBP) can protect the cultured primary cortical neurons from β -amyloid peptide neurotoxicity [108, 109]. We also found that LBP pre-treatment could effectively protect the retina from neuronal death, glial activation and oxidative stress in a murine retinal I/R model [110]. More importantly, oral LBP pre-treatment effectively improves neurological deficits, decreased infarct size and cerebral edema after MCAO-induced I/R injury. BBB disruption, aquaporin-4 upregulation and glial activation are attenuated by LBP pre-treatment [111]. These results suggest that LBP may be used as a prophylactic neuroprotectant in patients at high risk for ischemic stroke.

Magnolia Officinalis Rehder Et Wilson

Magnoliae Cortex is the dried bark of *Magnolia officinalis* Rehder et Wilson (China) and *Magnolia obovata* Thunberg (Japan) [112]. It is commonly prescribed in TCM for the relief of stroke, myocardial infarction, headache, anxiety, diarrhea and fever [113]. Many pharmacological activities of extracts from Magnoliae Cortex have been reported; these include muscle relaxation [114], central depressant effect [115], vasorelaxant [116], anti-allergic [117], anti-bacterial [118, 119], and neurite spouting activities [120].

Two active components, magnolol and its isomer, honokiol, have been isolated. Magnolol has been found to have anti-platelet effect [121], vasodilatation effect [116] and free radical scavenging activities [122]. In the heart, magnolol may protect the myocardium against ischemic injury and suppress ventricular arrhythmia during ischemia and reperfusion [113]. Magnolol also significantly attenuates the increase in striatal ischemia and damage markers associated with heatstroke [123]. Honokiol is also reported to have hydroxyl radical-scavenging [124] and anti-platelet effects [125]. It also inhibits the production of nitric oxide (NO) and TNF α in lipopolysaccharides (LPS)-activated macrophages [126]. In addition, it protects the rat heart and liver mitochondria against lipid peroxidation [122, 127]. Further studies show that honokiol is able to reduce infarct size and exhibit an anti-arrhythmic effect in rats subjected to coronary artery occlusion [113, 128, 129]. Moreover, both honokiol pre-treatment and treatment significantly reduce the infarction volume in rats subjected to focal cerebral ischemia [130].

***Paeonia Suffruticosa* Andrews, *Paeonia Lactiflora* Pall**

Both *Moutan cortex* of *Paeonia suffruticosa* Andrews and the root of *Paeonia lactiflora* Pall are common TCM herbs for treating inflammatory and pyretic disorders [131-133]. In particular, the root bark of *P. suffruticosa* Andrews is prescribed for treating blood stagnation [27]. It demonstrates strong superoxide- and hydroxyl radical-scavenging activity [134]. It also strongly enhances cell viability against hydrogen peroxide (H_2O_2)-induced oxidative damage, together with high levels of 1,1-diphenyl-2-picrylhydrazyl (DPPH) radical scavenging activity and enhanced activities of SOD, catalase (CAT) and GPx [135]. α -benzoyloxypaeniflorin is an antioxidant monoterpene glycoside isolated from *P. suffruticosa* Andrews. It also exhibits radical scavenging activity on DPPH radical [136].

The root of *P. lactiflora* Pall is commonly used in TCM to treat abdominal pain and blood deficiencies [27]. Previous studies showed that its extract and paeoniflorin, a major constituent of *P. lactiflora* Pall root, attenuate scopolamine-induced cognitive impairment [137]. Pre-treatment with paeoniflorin also significantly prevents the scopolamine-induced decrease in acetylcholine (ACh) content in the striatum [137]. Paeoniflorin ameliorates memory disruption mediated by adenosine A1 receptors, implicating its beneficial effect on learning and memory impairment in rodents by modulation of adenosine-mediated inhibition of long term potentiation (LTP) in the hippocampus [138]. Paeoniflorin post-treatment not only significantly reduces the infarct volume but also ameliorates the deficits in neurological symptoms caused by transient MCAO at the chronic stage [139]. Paeoniflorin is also shown to confer neuroprotection by activating adenosine A1 receptor in rat after transient MCAO [140]. Later studies show that both pre-treatment and post-treatment with paeoniflorin reduce the ratio of cerebral infarction area [141]. In particular, pre-treatment with paeoniflorin reduces the neurological deficit score together with an inhibition on the presence of ED1, interleukin-1 β (IL-1 β), tumor necrosis factor α (TNF α), ICAM-1 in microvessels and myeloperoxidase (MPO) immunoreactive cells, suggesting an anti-inflammatory effect of paeoniflorin [141]. Paeonol is a common component in the *Moutan cortex* of *P. suffruticosa* Andrews and the root of *P. lactiflora* Pall. It has been shown to be neuroprotective in ischemia/reperfusion injury. It displays antioxidant activities [142] and inhibits the aggregation of platelets in rabbits [131]. Paeonol is shown to protect cerebral ischemia by inhibiting accumulation of Ca^{2+} and production of oxygen free radical [143]. In cultured rat hippocampal neurons exposed to OGD, paeonol treatment increases cell survival rate and reverses the of intracellular Ca^{2+} overload [144]. Further investigations show that paeonol pre-treatment and post-treatment reduce the cerebral infarction area while paeonol pretreatment also reduces the neurological deficit, suggesting its potential in treating stroke patients [145]. Paeonol can scavenge superoxide anion as well as inhibit microglia activation and IL-1 β in I/R injured rats [145]. Post-treatment with paeonol reduces inflammatory responses in cultured LPS-activated microglia and oxidative stress-induced neurotoxicity in rat primary cortical neurons [146]. Paeonol also protects memory in rats after MCAO via reducing levels of amyloid precursor protein and β -secretase as well as apoptosis [147].

Panax Ginseng

Ginseng, the root of *Panax ginseng*, is a famous TCM. It is only used at least 4-6 years after cultivation in a variety of prescriptions. Numerous studies have demonstrated the usage of ginseng for 'Qi' invigorating and cardiovascular effects [27].

P. ginseng extracts decrease lipid peroxides and increase the expression of GPx and SOD, thereby protect against global ischemia injury in rat hippocampus [148]. Pre-administration of *P. ginseng* extracts protects against transient global cerebral ischemia in the rat [149] and gerbil [150].

Ginsenosides are the main active ingredients in *Panax ginseng* [27]. One of them, ginsenoside Rd, has demonstrated neuroprotective effects. Ginsenoside Rd rescues cultured hippocampal neurons that are exposed to OGD [151]. Besides attenuating apoptotic neuronal death, ginsenoside Rd also reduces the intracellular reactive oxygen species and MDA production, increases glutathione content as well as enhances the antioxidant enzymatic activities of CAT, SOD and GPx. Ginsenoside Rd can also stabilize the mitochondrial membrane potential [151]. Another ginsenoside, ginsenoside Rb1, also displays neuroprotective effects. Ginsenoside Rb1 protects the rat from focal cerebral I/R injury [152]. When given after forebrain ischemia, ginsenoside Rb1 protects hippocampal CA1 neurons against lethal ischemic damage possibly by scavenging free radicals [153]. In non-human primates, ginsenoside Rb1 has been shown to ameliorate both early and delayed injuries in the thromboembolic stroke model [154]. Interestingly, ginsenoside Rg1, unlike ginsenoside Rb1, has no effects in cerebral I/R injury [152]. Yet, ginsenoside Rg1 can increase ischemia-induced cell proliferation and survival in the dentate gyrus of adult gerbils after transient global ischemia [155].

P. notoginseng Burk is another herb from the same genus as *P. ginseng*. Its extracts have also demonstrated neuroprotective effects. *P. notoginseng* extracts attenuate the infarct size in ischemia rat brain, together with reduction in microglial activation and inhibition on production of inflammatory mediators, such as inducible nitric oxide synthase (iNOS) and cyclooxygenase (COX)-2 [156]. In particular, the saponins found in *Panax notoginseng* also demonstrate protective effects in cerebral ischemia [157, 158]. *Panax notoginseng* Burk can attenuate the reduction in learning and memory functions in rats with chronic stage ischemia-reperfusion injury, possibly by increasing the amount of activated microglia and brain-derived neurotrophic factor (BDNF) [159].

Pueraria Lobata

The dried roots of *Pueraria lobata* (Wild.) Ohwi have been widely used in TCM for centuries. The extracts are shown to have positive effects on I/R in the heart [160] and arterial obstruction in the retina [161]. Three major isoflavonoid compounds have been isolated from the extracts: puerarin, daidzin and daidzein [27]. Isoflavonoids in *P. lobata* have been shown to increase the cerebral blood flow in mice [162] and display anti-oxidative activities [163].

In vitro studies show that puerarin protects cultured mouse cerebral cortical neurons against glutamate excitotoxicity [164] and cultured rat cerebral cortical astrocytes against OGD [165]. The neuroprotective effect of puerarin on cultured hippocampal neurons after OGD is further shown to be associated with inhibition on glutaminergic transmitter, intracellular Ca²⁺ elevation and neuronal nitric oxide (NO) synthesis [166].

Puerarin can increase cerebral blood flow in dogs and attenuate cerebral or spinal ischemia/reperfusion injury in rats or rabbits [167, 168]. In rats subjected to MCAO, puerarin reduces the infarct volume and improves neurological function together with decreased caspase-3 activity, suggesting an inhibition of apoptosis [169]. The neuroprotective effect of puerarin is further linked with inhibition of excitatory amino acid efflux in rat after MCAO [170]. Moreover, the neuroprotective effect of puerarin is suggested to be mediated by

inhibition of hypoxia-inducible factor-1 α (HIF-1 α and TNF α , followed by the inhibition of inflammatory responses, apoptosis and neutrophil activation [171]. Recent investigations show that puerarin can reduce cerebral ischemic volume, relieve Ca²⁺ overload [172] and decrease the expression of NMDA receptor [173] while the time window for puerarin administration may be 12 hours after ischemic injury [172]. In a randomized controlled trial, the flavonoids of puerarin are shown to limit the increase of serum interleukin-6 (IL-6) and enhance blood flow in the ischemic region [174].

Based on the *in vitro* studies and animal experiments, puerarin has shown effects that may be beneficial in the treatment of acute ischemic stroke. Previously clinical trials have been conducted to assess the efficacy and safety of puerarin. However, only one trial with a small number of patients (up to 2008) can be included according to the present standard of clinical research and this trial cannot provide evidence for recommendation of routine puerarin use in all patients with acute ischemic stroke [175].

Rhodiola Rosea L., Rhodiola Sacra S. H. FU, Rhodiola Sachalinensis A. BOR

Rhodiola Radix is a Tibetan folk medicine prepared from several alpine *Rhodiola* plants and is used as a hemostatic, tonic and contusion [176]. It has been reported that *Rhodiola* plants improve learning and memory [177].

Salidroside is one of the most potent compounds in *R. rosea* L. [178] and has long been used as an adaptogen in TCM. Diverse pharmacological activities have been reported for salidroside, including anti-oxidation [179], anti-aging [180], anti-fatigue [181], and anti-carcinogenic [182]. Potent neuroprotective activity has also been described for salidroside recently. Salidroside exhibits protective effects against e.g., hydrogen peroxide-induced apoptosis in SH-SY5Y cells [183], hypoglycemia and serum limitation induced cell apoptosis in cultured PC12 cells [184], hypoxia-induced abnormal processing of amyloid precursor protein [185], and β -amyloid-induced oxidative stress in SH-SY5Y [186].

The extracts from 2 related plants, *R. sacra* S. H. FU and *R. sachalinensis* A. BOR, have also been tested in previous studies. Several components are shown to exert protective effects against cell death induced by either β -amyloid, staurosporine or H₂O₂ [187]. Phenolic compounds isolated from the roots of *Rhodiola sachalinensis* also exhibit significant scavenging effects against DPPH free radicals [188]. Moreover, *Rhodiola sachalinensis* extracts show neuroprotective effects on transient focal cerebral ischemia in rats [189].

Salvia Miltiorrhiza Bunge

The dried root of *Salvia miltiorrhiza* Bunge is known as *Radix salviae miltiorrhizae* (Danshen, also known as Tanshen in Japanese and some older literature) [190]. It is red in color and is commonly used in treatment of disorders related to blood stasis [27]. According to TCM theory, cerebral infarction is a result of blood stasis; therefore, one treatment of cerebral infarct is to quicken the blood and disspell the stasis [191]. Clinical trials indicated that Danshen was an effective medicine for angina pectoris, myocardial infarction and stroke [192].

In the United States and Europe, Danshen products can be purchased from herbal shops. In China, Danshen is available in various pharmaceutical forms, including tablets, capsules, granules, injectables, oral liquids, sprays, and dripping pills [193-196]. These various forms contain either Danshen alone or a composite of *Salvia miltiorrhiza*, *Panax notoginseng*, and

Cinnamomum camphora (known as Fufang Danshen) [193-195]. Among them, the two most commonly used forms are the Fufang Danshen Tablet and Fufang Danshen Dripping Pill. They have been officially listed in the Chinese pharmacopoeia [197]. Moreover, the Fufang Danshen Dripping Pill was the first TCM product approved for phase II and phase III clinical trials by the Food and Drug Administration (FDA) in 1997 (IND No.56956) [198].

The beneficial effects of Danshen on ischemia have been demonstrated. Danshen in experimental studies dilates coronary arteries, increases coronary blood flow, and scavenges free radicals in ischemic diseases [192]. In cerebral ischemia, Danshen attenuates the dysfunction of substance P [199] and improves ischemic cell changes by modulating somatostatin metabolism [200]. In addition, Danshen significantly decreases the stroke index by inhibiting the pre-synaptic releasing of glutamate and stimulating the releasing of γ -aminobutyric acid (GABA) in gerbils after common carotid artery ligation [201]. In a 4-vessel occlusion and reperfusion rat model, Danshen increases the cerebral SOD activity while decreasing the cerebral MDA level, suggesting that Danshen can reduce the lipid peroxidation and provide protection against cerebral reperfusion injury [202]. Further studies show that Danshen reduces the cerebral NO concentration to normal levels [203]. Both Danshen pre-treatment [204] and post-treatment [205] can reduce cerebral infarct size while Danshen post-treatment can also improve regional cerebral blood flow (rCBF) in the ischemic hemisphere and inhibit platelet aggregation in rats [205].

Zhou et al. have well covered the chemistry and pharmacology of Danshen [196]. Usually extracts in TCM herbs are aqueous extracts. However, for Danshen, the preparation is traditionally made with wine and fat for increasing the content of fat-soluble substances [190]. Recent studies show that Tanshinones are the major lipid soluble pharmacological constituents of Danshen, giving Danshen the reddish color and are selectively enriched in the traditional Danshen preparation [206]. With administration of tanshinones IIA (TsIIA) and IIB (TsIIB), there is a reduction in brain infarct volume accompanied by a significant decrease in the observed neurological deficit [190].

The evidence points to the possible role of Danshen in the prevention and treatment of cerebral ischemia [196, 207]. It appears that multiple pathways such as anti-atherosclerosis, anti-hypertension, anti-platelet aggregation as well as anti-inflammatory and anti-oxidative activities are involved [208, 209]. Some clinical trials of Danshen treatment in ischemic stroke have been carried out [196, 207, 210, 211]; yet, the quality of these trials is poor with minimal/no reliable conclusions [210, 212]. Large randomized controlled trials and further scientific research of high quality must be performed to ensure the safety and efficacy of Danshen in treatment of ischemic stroke [196, 212].

Schisandra Chinensis

In TCM, the fruit of *Schisandra chinensis* is used as an anti-tussive, tonic and sedative agent to improve liver and kidney function [27]. Similar to other herbs, *S. chinensis* can inhibit thiobarbituric acid reactive substances (TBARS) formation *in vivo* [213]. Several active components have been identified; these include schisandrin derivatives as well as lignans-schisandrol A, B and C [27]. Pre-treatment of schisandrin B provides cardioprotection in isolated-perfused rat hearts, may be by modulating the I/R-induced changes in non-enzymatic antioxidant levels [214]. Moreover, lignans extracted from *S. chinensis* attenuates the neurotoxicity induced by L-glutamate in primary cultures of rat cortical neurons,

suggesting that *S. chinensis* may possess therapeutic potential against oxidative neuronal damage induced by excitotoxin [215].

Scutellaria Baicalensis

The root of *Scutellaria baicalensis* Georgi (Huang-Qin) is commonly used in TCM as an anti-inflammatory drug and smooth muscle relaxant. It has also been used to treat stroke based on its ability to clear away internal heat [216]. In a rat transient global ischemia model, the methanol extracts from the dried roots of *S. baicalensis* Georgi significantly protect CA1 neurons and inhibit microglial TNF α and NO production. These extracts also protect PC12 cells from H₂O₂-induced toxicity *in vitro* [216].

Previous investigations confirmed that the active components in the root of *S. baicalensis* Georgi are flavonoids [217]. There are 4 major flavonoids, namely wogonoside and its aglycone wogonin as well as baicalin and its aglycone baicalein. The first flavone isolated from its root was wogonin. Wogonin is present only in small amounts in the root while baicalin predominates by far [216]. Out of these 4 flavonoids, baicalin and baicalein can effectively protect SY5Y cells from H₂O₂-induced injury while the effect of wogonin is marginal and wogonoside shows no effect [217].

In cultured primary neurons exposed to either glutamate stimulation, both baicalin and baicalein significantly reduce glutamate-increased lactate dehydrogenase (LDH) release, in which baicalein is much more potent than baicalin. Glutamate-increased intracellular Ca²⁺ is also significantly attenuated by baicalin and baicalein. In neurons exposed to glucose deprivation, baicalein but not baicalin show significant protective effects [218]. These results suggest that baicalein is the most effective compound. Baicalein also displays a radical scavenging effect *in vitro* and a neuroprotective effect *in vivo* by inhibiting hippocampal neuronal death in gerbils after transient cerebral ischemia [219]. On the other hand, baicalin administration can attenuate the elevations of glutamate and aspartate after MCAO in rat, suggesting that baicalin may act as a neuroprotectant during cerebral ischemia [220].

Wogonin has been reported to be neurotoxic in the brain [218]. However, *in vitro* studies showed that wogonin inhibits LPS-induced activation of cultured microglia, leading to a reduction in microglial cytotoxicity toward co-cultured PC12 cells, thereby supporting a neuroprotective role for wogonin [221]. In both experimental brain injury models of transient global ischemia and excitotoxic injury, wogonin attenuates hippocampal neuronal death and the neuroprotective effect is associated with inhibition of microglial activation [221].

Sophora Japonica L.

The dried flowers and buds of *Sophor japonica* is a TCM that can cool blood, stop bleeding and most often used to treat hemorrhoids with bleeding [222]. It is also used in Japan and Korea to treat hemorrhoids and hematemesis [223]. There are numerous components in *S. japonica*; the main ones include flavones, tetraglycosides, isoflavones, isoflavone tetraglycosides, triterpene glycosides, phospholipids, alkaloids, amino acids and polysaccharides [224]. *S. japonica* also contains five main flavonoids of rutin, quercetin, isorhamnetin, isorhamnetin, genistein and kaempferol [224]. Previous studies show that *S. japonica* can reduce the cerebral infarction area and neurological deficit induced by I/R in rats, together with a significant reduction in ED1 and IL-1 β immunoreactive cells as well as apoptotic cells, suggesting that *S. japonica* may reduce cerebral infarction partly as a result of

its anti-inflammatory activities [225]. It is later found that polysaccharides of *S. japonica* scavenge hydroxyl and superoxide anion free radicals [226], suggesting an anti-oxidative effect of *Sophor japonica*. Further studies demonstrate the effects of *S. japonica* on platelet aggregation and cardiovascular function, suggesting its potential as a treatment for cerebral infarct in humans [223, 227].

***Stephania Tetrandra* S. Moore**

The dried root of *Stephania tetrandra* S. Moore, *Radix Stephaniae tetrandrae*, contains an active ingredient, tetrandrine. Tetrandrine has a Ca^{2+} antagonizing property. Pre-treatment with tetrandrine has protective effects against I/R brain damages in gerbils [228]. In rats with MCAO-induced I/R injury, tetrandrine inhibited neutrophilic recruitment, expression of ICAM-1 mRNA and activation of NF- κ B [229].

Herbal Prescriptions in TCM

In TCM, the medicine is usually given to patients in formulas or prescriptions containing a mixture of herbs, with either main or accessory roles. Examples of some well-known prescriptions are described below. They have been shown to display safety and efficacy as well as neuroprotective effects both *in vivo* and *in vitro*.

***Buyang Huanwu Decoction (BYHWD)* 补阳还五汤**

Buyang Huanwu decoction (BYHWD) is a famous classic TCM formula for improving neurological functional recovery from stroke-induced disability. It is created by WANG Qing-ren (王清任) [230] and has been used in China for over 300 years [231]. BYHWD is composed of Astragalus root (*Astragalus membranaceus* in Latin, Huangqi in Chinese, from the family Fabaceae); Chinese Angelica root (*Angelica archangelica* in Latin, Danggui in Chinese, from the family Apiaceae); Red Peony root (*Paeonia lactiflora* in Latin, and Chishao in Chinese, from the family Paeoniaceae); Szechuan Lovage root (*Rhizoma ligustici Chuanxiong* in Latin, Chuanxiong in Chinese, from the family Umbelliferae); Peach Seed (*Semen persicum* in Latin, Taoren in Chinese, from the family Rosaceae); Safflower (*Gnecos* in Latin, Honghua in Chinese, from the family Asteraceae); and Earthworm (*Lumbricus* in Latin, Dilong in Chinese, from the family Lumbricidae). These components are mixed in the above order the ratio of 120:6:6:3:13:3:3 (dry weight) [232].

Numerous studies including clinical trials as well as *in vivo* and *in vitro* experiments have been conducted to further confirm the efficacy of BYHWD treatment and to elucidate the mechanism of BYHWD-mediated neuroprotection. In clinical trials, BYHWD can improve the metabolic imbalance of endothelin and calcitonin gene related peptide in aptients with early cerebral infarction [233]. More importantly, BYHWD can improve neurological function and quality of life in patients convalescent from cerebral infarction [234]. In animals after experimental stroke, BYHWD is beneficial in improving neurological recovery of neurological function [235] and reducing cerebral damages [232, 235-249]. Some mechanisms of BYHWD-mediated neuroprotection have been proposed. For example, heat shock protein 70 (hsp70) upregulation was decreased by BYHWD treatment [238]. BYHWD

could also regulate the expression of glial fibrillary acidic protein (GFAP) in astrocytes [239]. Inhibition of caspase expression [240, 244], neuronal nitric oxide synthase (nNOS) activity [243] and ROS [241] is also observed with BYHWD treatment. BYHWD has also been shown to increase 5-bromodeoxyuridine (BrdU) and therefore promote neurogenesis in the ischemic brain [235, 245]. In addition, BYHWD inhibits the increase in blood-brain barrier permeability and water content, suggesting its modulation on cerebral micro-circulation after ischemia/reperfusion [248]. BYHWD is also suggested to protect the brain from ischemic injury by modulating the expression of pre-inflammatory mediators such as IL-1 β and TNF α [246]. Moreover, BYHWD could reduce I/R brain injury via inhibition of the thioredoxin system [250], [Ca²⁺] [251], free radical scavenger activity [252], and glutamate release [232]. An extensive study using integrative neurofunctional and genomic approaches further showed that BYHWD protects mice against stroke and extend their lifespan through its effects on a variety of genes. These include down-regulation of genes involved in inflammation, apoptosis, anti-angiogenesis and blood coagulation as well as upregulation of genes mediating neurogenesis and nervous development [249]. *In vitro* experiments show that BHD reduced apoptosis [253] by downregulating p53 and p21 gene expression [254] in cultured rat cortical neurons after hypoxia. BYHWD can also protect cultured Schwann cells from H₂O₂-induced oxidative injury, suggesting a possible association of BYHWD-mediated promotion of neural regeneration with its anti-oxidative activity [255]. Taken together, all of these evidences point to multiple mechanisms in BYHWD-mediated neuroprotection in brain ischemia.

Buchang Naoxintong Jiaonang (BNJ) 步长脑心通胶囊

The ingredients of Buchang Naoxintong Jiaonang (BNJ) include Radix astragali, Radix angelicae sinensis, Radix Paeoniae Rubra, Radix Salviae miltiorrhizae, Rhizoma chuanxiong, Semen persicae, Flos carthami, Resina Olibani, Myrrha, caulis spatholobi, Radix achyranthis bidentatae, Ramulus cinnamomi, Ramulus mori, Pheretima, scorpio, and Hirudo. In fact, BNJ consists of BYHWD plus Scorpio and Hirudo; it is therefore a compound preparation of BYHWD [256]. BNJ is an approved TCM for stroke [257]; it is widely used and is well tolerated. BNJ combined with aspirin can enhance the anti-platelet effect in patients with cardio-cerebrovascular diseases [258]. In a randomized, double-blind clinical trial involving 80 patients with apoplexy at convalescence stage, BNJ treatment improves the patients' daily abilities, blood fat and hemorheological indices, suggesting that BNJ has good efficacy in these patients [259]. BNJ also improves the viability of hypoxic primary cortical neurons and significantly reduces neuron apoptosis, suggesting that BNJ can protect cortical neurons from hypoxia-induced apoptosis [260].

Danqi Piantang Jiaonang (DJ) 丹芪偏袒胶囊

Danqi Piantang Jiaonang (DJ) is a TCM drug currently approved in China to improve stroke recovery and is widely available in hospitals in China. DJ is marketed in China as Danqi Piantan Jiaonang and internationally as NeuroAid. It has been evaluated in clinical trials, but the results were only partly published in Chinese medical literature [261]. In 2006, DJ was selected by the Chinese Ministry of Science and Technology as one of the projects in the Key Technologies Research and Development program that aimed at promoting the development of the most promising Chinese innovations [262]. A recent pooled analysis of 2

randomized double-blinded, controlled trials comparing the efficacy and safety of DJ and Buchang Naoxintong Jiaonang (BNJ, see above) was performed. The results show that DJ displayed good tolerability and superiority over BNJ, another traditional Chinese medicine also approved for stroke [263]. Yet, a large Phase III double-blind randomized, placebo-controlled trial of DJ is essential before such treatments can be recommended for general clinical use.

Huang Lian Jie Du Decoction (HHD) 黄连解毒汤

Huang Lian Jie Du decoction (HHD) is also known as Hwangryunhaedok decoction. There are 4 herbs in HHD; they are *Coptidis rhizoma*, *Scutellariae radix*, *Phellodendri cortex*, and *Gardeniae fructus*. It is usually used as a traditional herbal medicine for sedative activity, and for its hypotensive and anti-bacterial effects [264]. Recently, the involvement of HHD in neuroprotection is reported [265-268]. Oral pre-treatment of HHD once daily for 5 days protects against the impairment of learning and memory induced by transient cerebral ischemia. More importantly, HHD significantly protects against cerebral ischemia-induced reduction in the ACh content of the cerebral cortex, hippocampus and striatum, suggesting that the protective effects of HHD may be associated with preventing the decrease in the ACh content of the mouse brain [266]. In addition, oral HHD treatment for five weeks protects against ischemic neuronal death after transient forebrain ischemia by increasing the expression of Cu/Zn-SOD, suggesting that HHD may reduce the exposure of hippocampal neurons to oxidative stress [265]. In a rat model of cerebral I/R, the total infarction volume in the ipsilateral hemisphere is significantly lowered by treatment with HHD [267]. HHD also significantly inhibits MPO activity, an index of neutrophil infiltration in ischemic brain tissue [267]. Out of the four components in HHD, *Scutellariae radix* displays much higher inhibition on total infarction volume and MPO activity than that of the others. It is therefore suggested that *Scutellariae radix* plays a crucial protective role in ischemia-induced brain injury [267]. The results also suggest that the effect of *Scutellariae radix* is the result, in part, of baicalein, a compound contained in *Scutellariae radix* [267].

Kueichih Fuling Wan (KFW) 桂枝茯苓丸

Kueichih Fuling Wan (KFW) is a TCM prescription containing 5 herbal components: *Cinnamomi ramulus*, *Poria cocos* (Schw.) Wolf, *Prunus persics* (L.) Batsch, *Paeonia suffruticosa* Andr., and *Paeonia lactiflora* Pall. It is also known as Keishibukuryogan or Gui-zhi-fu-ling-wan. KFW is originally introduced by Chang Chung-Ching (張仲景) in his Chin-Kuei-Yao-Lueh (金匱要婦人妊娠證並治篇). It is found to be effective in the treatment of cerebral vascular disease in clinical applications [269]. It has been used to treat cerebral ischemia [191].

In rat cerebral ischemia/reperfusion, KFW helps to alleviate the injury [270] as well as increase SOD activity, reduce MDA content and relieve neurological deficits [271]. KFW can also inhibit microglial activation and IL-1 β release and reduce cerebral infarction size in rats with MCAO. [272]. In ischemic neuronal SHSY-5Y cells, KFW can also prevent ROS increase and mitochondrial membrane potential (MMP) decrease. KFW can reduce lipid

peroxide formation and limit oxidative low density lipoprotein (LDL) modification, thereby preventing the progress of atherosclerosis in cholesterol-fed rabbits [273].

Qingkailing (QKL) Injection 清开灵注射液

In the 1970s, the Beijing University of Chinese Medicine modified a TCM, An Gong Niu Huang Wan (安宫牛黄丸), which is composed of *Radix isatidis*, *Flos Lonicerae*, *Concha Margaritifera Usta*, baicalin, *Fructus gardeniae*, cholic acid, hyodeoxycholic acid, and *Cornu Bubali*, and prepared Qingkailing (QKL) injection (清开灵注射液) [274]. In December 1992, QKL was listed in the ‘Practice Guide- line of Essential TCM Patent Drugs in Emergency Department of TCM hospitals, version 1’ [275].

Since then, the use of QKL has grown steadily. It has been extensively used to treat the acute stages of cerebrovascular disease and has shown beneficial effects in improving neurological function [276]. QKL injection has shown diverse pharmacological effects in animal studies, including reduction in Ca^{2+} overload, regulation of matrix metalloproteinase-9 expression and inhibition of inflammation [277-279]. Several clinical studies such as case reports and randomized clinical trials have reported the effectiveness of QKL injections, but no definite conclusion on efficacy and adverse events associated with QKL injection can be drawn after pooled analysis [280]. The lack of adequate evidence in safety assessment also limits the clinical use of QKL [281].

Later a refined formula of QKL, Refined Qing Kai Ling (RQKL), was developed. RQKL is an improved formula derived from the combination of effective and safety components in Qing Kai Ling injection [282]. It consists of cholic acid, hyodeoxycholic acid, baicalin, and jasmninoidin [283]. RQKL is neuroprotective by relieving the damage of vascular endothelial cell and inhibiting the inflammation [284] as well as promoting endothelial nitric oxide synthase expression [282].

Further investigations showed that RQKL can prevent ischemic-induced brain injury with a time window of 6 h, may be by suppressing ER stress-mediated apoptotic signaling [283].

Qizhu Tang Decoction (QZT) 芪术汤

Qizhu Tang (QZT) consists of four herbal components: *Rhizoma atracylodis macrocephalae*, *Poria cocos*, *Radix notoginseng*, and *Radix astragali seu hedysari*. It has been demonstrated to be effective in preventing cerebral oxidative injury in rats [285, 286]. It demonstrates marked anti-oxidative activities *in vitro* by scavenging DPPH and hydroxyl radical as well as inhibiting TBARS formation [285]. When the QZT decoction is injected into rat duodenum 2 hour before cerebral ischemia, TBARS formation and loss of GPx activities are inhibited, suggesting a prevention of oxidative brain damage [286].

Shengmai San 生脉散

Shengmai San (SMS) contains 3 herbal components: *Panax ginseng*, *Ophiopogon japonica* s and *Schisandra chinensis*. It is used mainly for treating coronary heart disease [287]. SMS is first shown to be effective in protecting the rat from cerebral ischemia/reperfusion injury by inhibiting brain edema, intracellular enzymes release, lactate accumulation and lipid-preoxidation [237]. Later studies showed that SMS pre-treatment

inhibits TBARS formation and loss of GPx activity in a rat model of forebrain I/R, thereby preventing cerebral oxidative damage [213, 288]. The anti-oxidant property of SMS is further shown in PC12 cells [289]. SMS pre-treatment also protects rats against heat stroke-induced arterial hypotension and cerebral ischemia by inhibition of iNOS-dependent production of NO and prevention of excessive accumulation of inflammatory cytokines in the peripheral blood stream [290]. These results indicate the potential of SMS as a stroke therapy by inhibiting oxidative damage and preventing cell death.

Acupuncture

In China, more than 30% of patients experienced stroke attack have been treated with traditional medicine, either with traditional Chinese herbs or acupuncture [291]. Many *in vivo* studies have demonstrated that acupuncture could induce either local or long-distance biochemical effects by stimulating sensory neurons [292]. In the basic studies, Zhang et al. reported an interesting observation on Sprague–Dawley rats that were induced to have cerebral ischemia. He treated the rats with electro-acupuncture at the acupuncture point *Baihui*, somewhere located at the cross point of the sagittal mid-line and the line connecting the ears, and used magnetic resonance imaging to examine cerebral edema. It was found that electro-acupuncture could alleviate cerebral edema following the ischemic injury [293].

In clinical studies, Cheng et al. chose 60 patients with post-stroke hand dysfunction and compared the therapeutic effects of acupuncture with routine medicine and physical therapy. Improved scores of hand function and walking ability are found in the acupuncture group, indicating the enhancement of living quality by acupuncture [294]. Hsing's group observed 62 patients with ischemic stroke and treated them with subcutaneous acupuncture over the scalp. They found an improved functional recovery with the acupuncture treatment when compared with the sham group [295]. Several systematic reviews on the safety of acupuncture for ischemic stroke have been published [296–298]. Park et al. concluded that there is no compelling evidence to show that acupuncture is effective in stroke rehabilitation [296]. A later report by Sze et al. showed that with stroke rehabilitation, acupuncture has no additional effect on motor recovery but has a small positive effect on disability [297]. The analysis by Zhang et al. concluded that acupuncture appears to be safe but without clear evidence of benefit [298]. All 3 analyses agreed that larger clinical trials with better study design are essential.

TRADITIONAL CHINESE MEDICINE – WEAKNESS

In Western medicine, industrially manufactured pharmacological drugs are used. In TCM, unlike the Western medicine, extracts and prescriptions are mostly used in which the active ingredients and components are usually not identified, specified and measured. This has led to great variations among batches of herbal medicine, resulting in the difficulties in evaluating and comparing safety and efficacy in clinical trials [299]. Moreover, the results of most TCM clinical trials are published in local non-English journals, making their retrieval and appraisal more difficult. The problem is further worsened by the poor quality of most of

these reports [300]. In 2007, Wu et al. presented the first meta-analysis on the safety and efficacy of 59 traditional Chinese patent medicine (TCPM) listed in the Chinese National Essential Drug (CNED) of 2004 (<http://www.sda.gov.cn>) and those commonly used in China for ischemic stroke [301]. It was concluded that the methodological quality of most included clinical trials was “poor” and there was insufficient evidence of good quality on the effects of TCPM in the treatment ischemic stroke.

TRADITIONAL CHINESE MEDICINE – FUTURE DEVELOPMENTS

In light of the growing interest in TCM for the treatment of ischemic stroke, there is an urgent need in large-scale, properly designed randomized controlled trials followed by appropriate meta-analysis [299]. Since the use of TCM in a complex intervention in diseases, the study options suggested by Campbell and colleagues can be used [302]. The recently developed CONSORT guidelines are also suggested [299, 303, 304].

In addition, the Government of the People’s Republic of China has played major roles in defining the scientific principle and position of TCM. Numerous measures are being undertaken [305]. Recently, the Herbalome Project was formally proposed at the 103rd Eastern Forum of Science and Technology in 2007, providing a new theoretical basis for TCM research. Through the Herbalome Project, one can elucidate the constitution, structure and function of the herbs in TCM. A resource library of the various herbal substances will also be built. Most importantly, it should be noted that the research of TCM should not be considered as identical to that in Western medicine [305].

CONCLUSION

Stroke is a devastating disease and causes major social burden worldwide. Despite the vast diversity of investigations using *in vitro* and *in vivo* experimental models as well as clinical trials, the lack of effective and widely applicable pharmacological treatments for ischemic stroke patients persists. Many people have turned to the traditional medicine that has abundant clinical data as well as extensive observational and anecdotal experiences in the hope of identifying effective treatments. Experience on the usage of TCM has been inherited and accumulated over thousands of years and has been used in treatment of ischemic stroke. Its safety and efficacy, although not proven according to the present standards, should not be doubted. Yet, further scientific research of high quality as well as large-scale, properly designed randomized controlled trials followed by appropriate meta-analysis are necessary and essential before such treatments can be recommended for general clinical use.

Chapter 10

ISCHEMIC STROKE IN CHILDREN: SYMPTOMS, PREVENTION AND RECOVERY

Mubeen F. Rafay

Children's Hospital, Winnipeg, University of Manitoba, Manitoba, Canada

ABSTRACT

Arterial ischemic stroke (AIS) is a rare neurological disorder among the pediatric population. Its long-term sequelae include motor and sensory impairments, behavioural and psychiatric problems, cognitive deficits and epilepsy. Clinicians treating pediatric AIS are often presented with significant management challenges due to mistaken or delayed diagnosis and the need for better evidence regarding its management. Long-term sequelae of pediatric AIS include motor and sensory impairments, cognitive deficits, behavioural and psychiatric problems and epilepsy.

Current therapeutic strategies for pediatric AIS focus on supportive therapy and secondary prevention with anticoagulation or anti-platelet therapy in those with increased risk of recurrence. In children with AIS, the role of fibrinolytic therapies, such as tissue plasminogen activator, in the management of acute stroke remains unclear due to the lack of randomized control trials and lack of evidence for its safety and efficacy in pediatric populations. As such, comprehensive studies to guide the management of pediatric AIS are critically needed to improve outcomes as they present significant morbidities to both patients and their families. In this chapter, the current literature with regards to the risk factors and etiologies of pediatric AIS such as congenital heart disease, sickle cell disease, arteriopathies and prothrombotic disorders will be reviewed. In addition, maternal and fetal risk factors such as infertility, placental abnormalities and infection will be discussed as they have been found to be associated with neonatal AIS. Finally, the various clinical presentations and outcomes of pediatric stroke will be summarized, focusing at large on the importance of recognizing signs and symptoms of AIS well in advance for clinicians to administer prompt diagnostic and treatment interventions and not be faced with challenges of missed or delayed diagnosis.

INTRODUCTION

Ischemic stroke is one of the many principal causes of death and disability in children. In the past, ischemic stroke was considered to be a rare occurrence in children when compared to the adult population. However with time and improved understanding and advances in neuroimaging techniques, proper recognition and diagnosis of stroke in children has been accomplished. Multiple causes and risk factors are implicated in the etiology of ischemic stroke in children.

Ischemic stroke that occurs during childhood can be categorized as either childhood stroke (occurring between 1-month and 18-years of age) or ischemic perinatal stroke (occurring between 20-weeks of fetal life through the 28th postnatal day). Notably, the timeline of occurrence for ischemic perinatal stroke can be divided into three categories. The first category being fetal ischemic stroke, diagnosed before birth by using fetal imaging methods or in stillbirths based on neuropathologic examination. The second is neonatal ischemic stroke diagnosed after birth and on or before the 28th postnatal day including preterm infants. Finally, the third being presumed perinatal ischemic stroke, diagnosed in infants more than 28 days of age in whom it is presumed but not certain that the ischemic event occurred sometime between the 20th week of fetal life through the 28th postnatal day [1] (Figure 1).

As in adults, the ischemic stroke subtypes in children include: arterial ischemic stroke (AIS) that is caused by occlusion or stenosis of the cerebral arteries and cerebral sinovenous thrombosis (CSVT) that is caused by occlusion of the cerebral veins or venous sinuses. In adults, the development of standardized AIS classifications and terminologies has greatly helped clinicians and researchers to determine outcomes, recurrence risk and treatment choices for different AIS subtype. For childhood AIS, no such classification system existed until recently, when a consensus based classification system for childhood AIS was developed for the first time. This classification system, known as the Childhood AIS Standardized Classification And Diagnostic Evaluation (CASCADE) criteria, was developed by a group of international pediatric stroke study investigators to standardize and facilitate both clinical care and data collection methods for childhood AIS [2]. In addition, to facilitate research in cerebrovascular disorders, the National Institute of Neurological Disorders and Stroke recently supported an initiative that led to the development and publication of the stroke-specific Common Data Elements (CDEs) for both adults and children [3].

In the present chapter, ischemic stroke subtypes in the pediatric age group are reviewed with particular emphasis on the clinical presentation, causative and risk factors, treatment and preventative strategies and outcomes in children with ischemic stroke.

ARTERIAL ISCHEMIC STROKE

Arterial ischemic stroke (AIS) is defined by the presence of persistent focal neurological deficit of acute onset and neuroimaging evidence of focal parenchymal infarct or infarcts conforming to corresponding arterial territory (Figure 2). These focal neurological deficits in infants can be seizures alone or other signs of encephalopathy e.g., extreme irritability or alteration in consciousness. In some children, focal neurological deficits are transient, lasting

less than 24-hours. When there is no neuroimaging evidence of new focal area(s) of infarction and the event is not due to other etiologies (e.g., seizure, migraine) the event is then considered to be a transient ischemic attack (TIA).

Figure 1. A 6 months old infant with presumed ischemic perinatal stroke who presented at the age of 6 months with infantile spasms and evidence of right sided pathologic handedness and left moderate hemiparesis. A, B and C) MRI brain on axial T1, T2 and FLAIR sequences demonstrating cystic gliosis and ex-vacuo dilatation of the right lateral ventricle in the territory supplied by the right middle cerebral artery.

Figure 2. A term infant with complete acute left middle cerebral artery territory ischemic stroke who presented few hours after birth with apneas and right hemibody focal seizures. A and B) Axial diffusion weighted MRI brain demonstrating diffusion restriction in the left frontal and parietal lobe regions and basal ganglia with corresponding apparent diffusion coefficient map consistent with an acute ischemic infarction involving the left middle cerebral artery territory.

In children, the reported incidence of AIS ranges from 0.6 to 7.9 per 100,000 children per year [49] with higher incidence among males and black Africans [10-12] (Table1). Over half of the strokes occur in children less than one year of age [8]. The estimated incidence varies widely depending upon the types of studies that are conducted. Population based studies have reported lower incidences whereas studies based on hospital discharge databases have shown higher incidences [6, 13-16]. Schoenberg and colleagues were the first to report a population based incidence of 0.6 per 100,000 children per year [16]. Subsequent population based studies have reported increased incidence rates for AIS in children ranging from 2.6 to 7.9 per 100,000 children per year [6, 13-15]. In the United States, a national study of hospital discharge database for children with ischemic stroke, revealed an estimated incidence of 7.8 per 100,000 children per year [8]. In Asia however, studies based on hospital database have estimated much higher incidences, up to 29.7 per 100,000 children per year [4]. Irrespective of the type of study, over time, pediatric literature has indicated an overall increase in the incidence of childhood AIS. This apparent increase in incidence is likely related to increased awareness of the disorder among clinicians, improvements in imaging techniques used for the diagnosis of stroke, increasing survival in previously fatal disorders and the increased use of therapeutic interventions to treat most of these disorders (such as complex congenital cardiac conditions). Additionally, the increased incidence seen in reports based on hospital discharge databases is likely due to the fact that most of these hospitals serve as tertiary care centers and have large catchment areas that serve multiple regions within the state or the country.

CLINICAL PRESENTATION

The clinical presentation of AIS in children is related predominantly to the age of the child and the location of the infarction. The onset of symptoms is variable, either with abrupt onset or with stuttering symptomatology. However, in majority of children the symptoms are subtle and often non-specific. Even if children present with stroke specific symptoms such as focal neurological deficits, the presenting symptoms are often attributed to other neurological disorders that are commonly seen in children, such as seizures with ictal or post-ictal Todd's paresis, complicated migraine, intracranial tumor or hemorrhage, infection or demyelination. In addition, seizures, fever, lethargy and headache are more common in children with AIS [17, 18]. As a result, the diagnosis of ischemic stroke in children is often missed and not considered as the first diagnostic consideration by the frontline medical and paramedical staff.

Young infants with acute ischemic stroke usually present with seizures, irritability or altered consciousness. Presentation with hemiparesis may be present but is often difficult to recognize in this age group. Toddlers typically present with acute neurological deficit (usually hemiparesis and/or facial droop) and seizures. Older children can present with other neurological deficits such as speech, visual, focal sensory abnormalities, ataxia or headache in addition to hemiparesis and facial weakness [14, 19].

As in adults, the presentation of ischemic stroke in children differs based on the location of ischemic infarction which is determined by the vascular territory and the circulation involved. The areas of the brain supplied by the internal carotid arteries and their branches (main branches include middle and anterior cerebral arteries) comprise the anterior circulation and the areas supplied by the vertebrobasilar system (vertebral and basilar arteries and their

branches) constitute the posterior circulation. Children with infarction in the middle cerebral artery territory typically present with sudden onset hemiparesis with or without facial weakness or speech abnormalities. Anterior cerebral artery territory events usually present with predominant contralateral leg weakness compared to arm or leg weakness alone. In addition to the contralateral hemiparesis, infarcts isolated to the basal ganglia can present with contralateral movement disorders, such as hemidystonia or chorea [20]. Posterior circulation ischemic strokes are less common in children and account for less than 10% of ischemic stroke cases [21]. Visual deficits are common with posterior cerebral artery territory events or with involvement of the optic pathway. Vertebral and basilar artery ischemic strokes typically present with vomiting, vertigo, headache, alteration in consciousness, coordination difficulties, hemiparesis or asymmetric quadriparesis and papillary, oculomotor and bulbar manifestations [21, 22].

Table 1. Annual Incidence Stroke in Children

Studies	Year Reported	Annual Incidence of Stroke [†]	Arterial Ischemic Stroke Incidence	Number of Stroke Patients
USA (Rochester) [16]	1978	2.5	0.6	4
USA (Cincinnati) [13]	1993	2.7	1.2	16
Europe (Dijon) [15]	1995	13	7.9	28
Iran (Khorasan) [7]*	1999	1.8	17	17
USA [8]*	2002	11.9	7.8	1377
USA (California) [11]*	2003	2.3	1.2	2278
Hong Kong [5]*	2004	2.1	36	50
Canada [6]	2006	0.7	2.6	820
Saudi Arabia (Al-Khobar) [4]*	2007	29.7	28	31

* Based on hospital admission and discharge database.

[†] Cases per 100,000 children population per year for both hemorrhagic and ischemic strokes.

Although the majority of children with AIS present with a single episode of focal neurological deficit, recurrent transient or minor ischemic events may be present in about one third of children that later present with a major ischemic event or fixed neurologic deficit. In children, prompt evaluation with neuroimaging is important since TIA recognition and differentiation from other disorders with similar brief neurological events such as seizures and migraines can be clinically challenging [23].

For children presenting with symptoms suggestive of AIS diagnosis, early and specific parenchymal neuroimaging is required to differentiate from other neurologic conditions and establish a definitive AIS diagnosis. The head computed tomography (CT) has easy accessibility as well as ability to readily rule out intracranial hemorrhage and mass lesions. It is for these reasons that head CT scan is often the first neuroimaging test that is completed in children that are suspected of AIS or other focal brain lesions. However, compared to magnetic resonance imaging (MRI), CT scan has low resolution and may miss the signs of early infarction, especially when done within 12 hours of ischemic stroke symptom onset. When available and feasible, brain MRI with diffusion weighted sequences is the specific and

preferred neuroimaging test for the diagnosis of AIS in children. Since identification of an arteriopathic condition or occlusive clot will determine initial treatment intervention, it is advised that in all clinically suspected AIS cases, non-invasive vascular imaging, utilizing either CT or MR angiography, should be included in the initial neuroimaging work-up. Subsequent to the initial diagnostic neuroimaging test, selected cases may require invasive conventional catheter cerebral angiography, particularly when initial non-invasive vascular imaging suggests vascular occlusion, arteriopathy or is inconclusive of these diagnoses.

Etiologies and Risk Factors

Once the AIS diagnosis is confirmed, an aggressive and timely search for the underlying etiologies and risk factors for AIS is recommended since conditions that predispose to stroke may themselves require urgent treatment and are closely linked to the risk of AIS recurrence and poor outcomes in children [24, 25]. The etiologies and risk factors of childhood AIS differ significantly from those in adults [19]. In adults, the leading causes of AIS are: atherosclerosis, hypertension, cardiac dysfunction (in particular atrial fibrillation) and small vessel diseases. In children, congenital cardiac disease or cardiac intervention, arteriopathies, central nervous system infections and prothrombotic and hematological disorders, are common identifiable risk factors for AIS. A number of these contributing factors may coexist in a child with AIS [25]. It should also be noted that, in spite of a thorough and systematic search for an underlying etiology, in at least half of the children with AIS, an etiology or risk factor for AIS is not identified [26]. Depending upon the populations studied and breadth of etiological investigations carried out by the different care centers, the reported occurrence of the potential etiologies and risk factors for AIS vary considerably in children. Recent studies have identified risk factors in over 70% of children with AIS [27]. The commonly associated etiologies and risk factors for AIS in children are briefly discussed below and listed in Table 2.

Cardiac Disease or Intervention

Cardiac disease or intervention leading to cardioembolic stroke is one of the most common etiologies for AIS in children. In a prospective population based study and several case series, a cardiac disorder was present in 20 to 28% of children with AIS [6, 25, 26]. In adults, atrial fibrillation, myocardial ischemic dysfunction and valvular disease constitute the common causes for cardioembolic stroke. In children congenital cardiac malformations with prominent intracardiac shunting, cardiomyopathies, arrhythmias and endocarditis are commonly responsible etiologies. The majority of AIS associated with these pediatric cardiac causes occur in the setting of a cardiac surgical procedure or diagnostic and interventional catheterization [26, 28]. In such circumstances, studies have reported highest risk of stroke occurrence in the first few years of life after the cardiac intervention has occurred [29, 30]. Most children with cardioembolic stroke present with sudden or abrupt onset focal neurologic deficits, headache, seizures or alteration in level of consciousness. In over half of the children, the symptoms are identified on awakening, usually from a medical sleep required for a cardiac intervention [31-33].

Table 2. Etiologies and Risk factors for Arterial Ischemic Stroke in Children

Cardioembolic Risk Factors	Prothrombotic Disorders and States
Acquired causes (e.g., dysrhythmia, atrial myxoma, bacterial endocarditis, rheumatic heart disease)	<i>Inherited Causes</i> Protein C deficiency
Congenital cardiac defects (e.g., ventricular hypoplasia, transposition of great arteries, Tetralogy of Fallot, septal defects, valvular defects)	Protein S deficiency Activated Protein C resistance Plasminogen disorders
Cardiac surgery or catheter intervention	Fibrinogen disorders
Hematological Disorders	Factor VII, VIII and XII elevations
Hemoglobinopathy (e.g., sickle cell disease)	Lipoprotein (a) elevation
Iron deficiency anemia	Lupus anticoagulant presence
Polycythemia	Antiphospholipid or anticardiolipin antibody presence
Essential thrombocythemia	Hyperhomocystenemia
Heparin induced thrombocytopenia	Factor V Leiden mutation
Thrombotic thrombocytopenic purpura	Prothrombin 20210A mutation
Vasculopathies	<i>Acquired Causes</i>
Moyamoya (disease, syndrome)	Cancer
Transient cerebral arteriopathy (e.g., post varicella angiopathy, other post infectious arteriopathies, idiopathic)	Procoagulant drugs (e.g., L-asparaginase) Nephrotic syndrome
Craniocervical arterial dissection	Metabolic and Genetic Factors
Traumatic	Organic acidemias
Infectious arteriopathies (e.g., secondary to meningitis, sepsis)	Mitochondrial disorders
Idiopathic focal segmental arteriopathy	Dyslipoproteinemia (e.g., hypercholesterolemia, hyperlipoproteinemia, Progeria)
Fibromuscular dysplasia	Fabry Disease
Radiation induced arteriopathy	Neurocutaneous disorders (e.g., NF1, Sturge Weber)
Diffuse CNS Vasculitis (primary, secondary)	Phaces syndrome
	CADASIL
	Connective tissue disorders(e.g., Ehler Danlos, Marfan)

Cerebral Arteriopathies

Childhood cerebral arteriopathies are disorders of the cerebral arterial wall abnormalities that can be either monophasic or have a progressive monophasic or undulant prolonged course [34]. Childhood cerebral arteriopathies reportedly predispose to AIS in approximately 30% to 60% of older children with AIS [6, 24, 26, 34] with much recent studies reporting higher rates [27]. However, considering that not all children with AIS receive appropriate vascular imaging and some may have false negative non-invasive vascular imaging, the occurrence of arteriopathy in children with AIS is likely underestimated. Arteriopathies in children can be inflammatory (related to infectious, post infectious or autoimmune mechanisms), genetic, structural, toxic or traumatic causes. International collaborations and

efforts are striving to better categorize and define these arteriopathies [2, 34, 35]. Improved and early use of neurovascular imaging in pediatric stroke (including both invasive and non-invasive imaging) over the years has greatly improved our understanding of different arteriopathic conditions. Additionally, recent non-invasive imaging techniques utilizing vessel wall imaging are showing promising findings in better defining and characterizing these arteriopathies [36]. Common arteriopathies associated with AIS in children include moyamoya, arterial dissection, focal cerebral arteriopathy (including transient cerebral arteriopathy of childhood and infectious and post infectious arteriopathies) and diffuse central nervous system (CNS vasculitis), are described below.

Moyamoya disease reportedly affects all ethnic populations, but predominantly Japanese and other Asian populations. It is a rare progressive vaso-occlusive cerebrovascular disorder of unknown etiology. It is characterized by stenosis and occlusion of the arteries at the base of the brain with abnormal tangiectatic collateral circulation [37] (Figure 3). Most often, moyamoya disease is sporadic but some familial clustering is reported. Additionally, moyamoya is seen in association with other medical conditions and is then called as moyamoya syndrome. The disorders commonly associated with moyamoya syndrome include genetic syndromes, (Down's syndrome Allagile syndrome, Williams syndrome), neurocutaneous disorders, post radiation exposure, hemoglobinopathies and renovascular abnormalities [38]. The younger children with moyamoya typically present with recurrent ischemic strokes that are often transient and occur in association with hyperventilation. On the other hand, older children with moyamoya present with hemorrhagic strokes. The clinical symptoms are variable and dependent upon the type and the location of stroke. In moyamoya, focal neurological deficits are common in children with ischemic stroke presentation and signs of raised intracranial pressure are common in children with hemorrhagic stroke presentation, such as alteration in level of consciousness, headache and vomiting.

Craniocervical arterial dissection is a well established etiology for stroke during childhood. The reported frequency varies from 7%- 20% [39-42] with some studies reporting a male predominance [40]. Prominent presenting features include, head and neck pain, alteration in level of consciousness and focal motor neurological deficits. Horner's syndrome, commonly reported in adults, is not frequently noted in children [41]. Head and neck trauma leading to arterial wall tear can occur spontaneously and is the responsible mechanism in over half of the children with craniocervical arterial dissection [39-41]. Apart from trauma, other predisposing factors for craniocervical arterial dissection include connective tissue abnormalities, fibromuscular dysplasia, anatomical variations, infections and hyperhomocysteinemia [40]. Characteristic vascular findings that support a diagnosis of dissection include the following: focal segmental irregular stenosis of a large vessel in the presence of aneurysmal dilatation (pseudo aneurysm), presence of an intimal flap, double lumen and or bright crescent sign (on axial fat saturated T1 sequence of magnetic resonance imaging) or occlusion of a cervical artery or a vertebral artery at either C1-C2 or C2-C3, with a history of preceding head or neck trauma (within two weeks of presentation) [40, 41].

A strong relationship between arteriopathies secondary to infection is noted in children with AIS. Commonly reported infections that may lead to direct arteriopathic abnormalities in children include bacterial meningitis, encephalitis and septicemia, infection with mycoplasma pneumoniae, Coxsackie's B4 and A9, parvovirus B19, influenza A and human immunodeficiency viruses [9, 43, 44]. Some inflammatory focal cerebral arteriopathies occur after an infection and are termed post infectious. Although common in children, the

pathogenic mechanisms for inflammatory focal arteriopathies are poorly understood in children. The examples of these inflammatory focal cerebral arteriopathies include transient cerebral arteriopathy of childhood (TCA) and idiopathic focal segmental arteriopathy. The TCA characterized by a monophasic course and preferential involvement of unilateral distal branches of the internal carotid artery and proximal branches of the anterior cerebral and middle cerebral arteries (the carotid T distribution) (Figure 4). The infectious agents involved with TCA include varicella zoster, Coxsackie's B4 and A9, parvovirus B19, influenza A and enteroviruses. Prior exposure to varicella zoster within the 12 months of onset of TCA (also known as the post varicella angiopathy) is implicated in at least half of the patients with TCA [35, 45].

All other segmental focal arteriopathies with unknown etiopathogenic mechanisms comprise the idiopathic group which is markedly heterogeneous and poorly studied. In addition, it is not uncommon to confuse clinical and radiological presentations of arterial dissection and early onset moyamoya with some the above mentioned focal arteriopathies [35].

Diffuse central nervous system vasculitis is defined as diffuse or multifocal areas of segmental narrowing and dilatation (beading) involving small or medium sized cerebral vessels. The diffuse CNS vasculitis can be either a primary angiitis exclusive to the central nervous system (a well defined angiographic and pathologic entity in pediatric stroke literature or secondary angiitis in association with systemic vascular inflammatory disorders such as systemic lupus erythematosus, polyarteritis nodosa, Behcets disease, Sjogrens syndrome, sarcoidosis, inflammatory bowel disease and a variety of other autoimmune disorders [46-49].

Prothrombotic and Hematological Disorders

Various prothrombotic and hematological disorders have been associated with ischemic stroke occurrence in children. The clinical symptomatology is not unique and is similar to general ischemic stroke presentations. Observation of the family history for these children may reveal presence of a similar disorder or a tendency for one or more of the family members to form clots. Sick cell disease is one of the most common hematological disorders associated with childhood AIS. Over 25% of patients that are homozygous for this hemoglobinopathy develop AIS. Although majority of children with sickle cell anemia suffer from their ischemic stroke events during an acute sickle crises, some children will have their strokes due to a secondary vasculopathy, often moyamoya [28, 50-52]. It is therefore important to monitor all children with sickle cell anemia for both vascular flow studies as well as progressive vascular abnormalities. Other hematological disorders associated with childhood AIS include iron-deficiency anemia [26, 53], polycythemia and thrombocytosis [54, 55].

Hypercoagulable states or thrombophilic disorders, both inherited and acquired, have been reported to occur in 20-68% of children with ischemic stroke [14, 26, 54, 56-58]. Studies have noted that variations in the occurrence of hypercoagulable abnormalities in children with AIS are due to the nature and extent of investigations undertaken, types of stroke investigated, and geographic and ethnic differences between studies [57, 59, 60]. Most commonly noted hypercoagulable abnormalities include: deficiencies of Protein C, Protein S,

antithrombin III and plasminogen; serum elevations of lipoprotein(a) and homocysteine; presence of antiphospholipid antibodies; mutations of factor V Leiden, prothrombin 20210A gene and methylenetetrahydrofolate reductase deficiency (MTHFR). Some of these coagulation abnormalities do not directly cause AIS but rather increase the risk of stroke by combining with other factors that trigger or predispose to AIS [61].

Genetic and Other Risk Factors

Apart from the already described and known genetic disorders that are associated with an increased risk for ischemic stroke (e.g., Fabry disease, Progeria, PHACES syndrome, etc.), an individual's personal and or familial genetic predisposition (either monogenic or polygenic) require further research [62, 63].

Other risk factors for AIS that are uncommon in children and are similar to the adult AIS patients include use of oral contraceptives and/or street drugs, particularly amphetamines and cocaine; personal history of migraines, and metabolic (carbohydrate deficient glycoprotein syndrome, homocystinuria) and lipid disorders [14, 23, 28].

Risk Factors for Ischemic Perinatal Stroke

During the perinatal period, cardioembolic, inflammatory and hypercoagulable conditions are relatively less common risk factors [8]. A number of placental, fetal and maternal factors play an important role in ischemic stroke etiopathogenesis during this period. Commonly reported maternal risk factors associated with perinatal stroke include presence of a prothrombotic condition (mainly positive antiphospholipid antibody status), infertility, primiparity, oligohydramnios, prolonged 2nd stage of labour, preterm labour, delivery via emergency C- section delivery or vacuum extraction, preeclampsia, and prolong rupture of membranes [8, 57, 64, 65]. A variety of placental pathologies are associated with an increased predilection for thrombus formation including vascular necrosis, hypoperfusion, chronic villitis, and, most commonly, chorioamnionitis, (which accounts for at least 10-15% of all live births.) [66, 67]. Fetal risk factors include male child and fetal heart rate and cord abnormalities. Furthermore, presence of multiple risk factors often coexists in the same individual infant, which confers greater risk for stroke in these infants. However, similar to older children, in at least 30% of ischemic perinatal stroke cases an underlying cause or risk factor for AIS occurrence may not be identified [8, 9].

TREATMENT AND PREVENTION OF CHILDHOOD AIS

There are no multicenter or randomized controlled clinical trials for the acute treatment or prevention of childhood AIS, except in children with sickle cell disease. Although systematic approaches to pediatric stroke care and research are emerging, these are still at very early stages. The treatment of childhood AIS is either extrapolated from the adult ischemic stroke literature or based on treatment approaches published in the pediatric case reports and cohort studies. The application and development of therapeutic interventions for stroke in children is therefore faced with many ethical and practical challenges for both the clinicians and the researchers. This led to the emergence of the recently published expert consensus based guidelines for the management of childhood AIS [44, 68-70]. It should be

noted that the evidence for most of the recommendations in these guidelines are class I (evidence or agreement that the procedure or treatment is useful and effective) or class II (conflicting evidence of divergence of opinion about the usefulness/efficacy of procedure or treatment) with level of evidence C (expert opinion or case studies) [44, 69, 70].

The therapeutic and preventative approaches for the treatment of childhood AIS in general as well as specific to some common ischemic stroke etiologies are discussed in the following section.

General Treatment of AIS

As in adults, the treatment of arterial ischemic stroke in children is twofold: acute and long-term preventative treatment.

Figure 3. An 11-year-old, previously healthy, right-handed girl with acute left basal ganglia ischemic stroke presented with slurred speech, decreased level of consciousness and right hemiparesis. A) Head computed tomography (CT) 8 hours after initial onset of symptoms revealed hypodensity in the region of the left lentiform nucleus consistent with an acute infarct. B and C) Magnetic resonance imaging (MRI) at 21 hours post-stroke demonstrated diffusion restriction in the left lentiform nucleus with a corresponding apparent diffusion coefficient map (B) in that region. D and E) Her contrast enhanced CT angiogram and MR angiogram were normal. F) A subsequent cerebral catheter angiogram demonstrated narrowing and irregularity in the distal segment of the left internal cerebral artery, proximal M1 segment of left middle cerebral artery and the A1 segment of the left anterior cerebral artery (arrows).

Figure 4. A 10-year-old, right-handed girl with left frontal old ischemic stroke who presented with a long-standing history of headaches with or without associated transient hemisensorimotor symptoms, frequently affecting left hemibody compared to the right side. A and B) MRI brain revealed evidence of volume loss on axial and coronal FLAIR sequences and (C) hyperintensity in the left frontal region on axial T2 sequences (arrows). The axial T2 sequences (C and D) and time of flight MR angiogram (E) reveal evidence of prominent tiny arteries and capillaries in the bilateral basal ganglia and parasagittal regions (arrows). F and G) The catheter cerebral angiogram on right and left internal carotid injections confirmed occlusion of bilateral distal internal cerebral arteries with reconstitution of the middle cerebral artery proximal segments via the deep arterial anastomosis and evidence of capillary collaterals and prominent hypertrophic deep perforating arteries giving the classical picture of moyamoya (or puff of smoke). G) The left vertebral artery injection show similar hypertrophic perforating arteries and new sprouting capillary collaterals.

Acute Treatment

The acute treatment is further categorized into hyperacute and sub-acute treatment. Hyperacute treatment strategies are targeted to the initial 6-hours and the sub-acute treatment to 6-hours to few days following the ischemic stroke symptoms onset.

Hyperacute Thrombolytic Therapy

Over the last two decades, adult literature has exploded with various thrombolytic and neuroprotective therapeutic interventions that may be used for the treatment of AIS during the hyperacute phase (typically within a narrow therapeutic window of 0-6 hours from the symptom onset). [71-73] However, many such therapies in adults are either experimental or not approved as standard of care treatment for AIS. Currently, in adults, systemic fibrinolytic therapy with tissue type plasminogen activator (t-PA or alteplase), given within the 4.5 hours of symptom onset, is the only approved standard hyperacute treatment of AIS. Intravenous administration of t-PA in adults with AIS was first shown to be effective in 2004, in a clinical trial funded by the National Institutes of Neurological Disorders and Stroke. This clinical trial clearly demonstrated that the group of patients who received t-PA within 3- hours of stroke symptom onset had significantly reduced disability from stroke compared to the placebo treated group (with 30% patients more likely to have minimal or no disability 90 days after

the treatment with t-PA), [73]. The trial noted that the risk of symptomatic intracranial hemorrhage was 6.4% when t-PA is instituted within the 3-hours therapeutic window compared with 0.6% in the placebo or the non-tPA treated group [73, 74]. However, a recent study in adults with ischemic stroke has demonstrated both safety and efficacy with the therapeutic window for intravenous t-PA extended to 4.5 hours leading to the recent approval of its use within 4.5 hours of stroke symptom onset in adults [75]. The other commonly practiced and favored hyperacute therapeutic interventions for selected adult stroke patients (although not yet standard of care treatment) is targeted intra-arterial administration of t-PA within 3-6-hours of ischemic stroke symptom onset [76]. This targeted and direct administration of drug into the thrombus reportedly has vascular recanalization rates up to 58% - 66% and an improved clinical outcome at 90 days in 31% - 40% of patients [76]. Other hyperacute interventions that have been studied in adults include clot busting interventions, such as use of mechanical clot retrieval devices (with recanalization rates as high as 57%), and neuroprotective strategies, such as whole body hypothermia or selective head cooling. These interventions have shown promising results but require further studies before these are widely adapted or approved for clinical use in adults with ischemic stroke [71, 72, 77-79].

Current pediatric literature reports either only single cases and few cohort studies or literature reviews/pooled analysis for the use of t-PA in the hyperacute phase of AIS [80-84]. In these studies, treatment with t-PA has reported efficacy rates as high as 50 – 80% in children with AIS, but with bleeding rates as high as 25% -50%. The bleeds were, however, mild and did not require transfusion therapy or any other intervention [85]. Since in children many age-related maturational, pathophysiological and developmental differences exist compared to adults, one cannot entirely extrapolate from adult studies. The development of systematic and randomized controlled studies involving these potentially beneficial hyperacute therapies are, therefore, of utmost importance in children with ischemic stroke. As a result, the much needed clinical trial to test the efficacy and safety of t-PA in children, the Thrombolysis in Pediatric Stroke (TIPS) study, was recently designed and developed, under the umbrella of the international pediatric stroke network. The TIPS study is a multicentre clinical trial approved and funded by the National Institute of Health. This study will systematically evaluate the safety and dose dependent efficacy of intravenous t-PA in children with AIS, aged 2-17 years. The t-PA will be administered intravenously in a peripheral vein within 4.5 hours of the onset of stroke symptoms. The intra-venous t-PA doses tested will have three dose tiers dependent upon toxicity (0.75, 0.9, 1.0 mg/kg), with 10% of the dose to be given as a bolus over 5 minutes and the remaining 90% given over one hour. Inclusion criteria will include clinical presentation with acute onset of neurological deficit in a pattern consistent with arterial territory ischemia with radiological confirmation via head CT or MRI and presence of partial or complete occlusion in an intracranial artery corresponding to the infarct location on CT or MR angiography [86] (and personal communication at the IPSS network meetings).

Although, recent advances in the treatment of pediatric ischemic stroke has resulted in promising avenues, one needs to be mindful of evidence based treatment approaches. All current published guidelines for the management of children with stroke are in agreement in not recommending hyperacute fibrinolytic therapy with t-PA for acute childhood AIS, except in the setting of a clinical trial and until much is known about the safe administration of this medication in children [44, 68-70].

It should also be noted that to be effective and safe, t-PA and other hyperacute treatments must be instituted within a narrow therapeutic window [71-74] requiring prompt and correct stroke diagnosis. Therefore, in adults, hyperacute diagnosis has become the major focus for education campaigns and research. In adults, major advances in acute stroke care have significantly reduced both the pre-hospital and in-hospital delays, delay in arrival to a hospital and receiving timely diagnosis and treatment for acute stroke continues to be a concern in adults [87-93]. In children suspected of AIS, timely and accurate diagnosis of AIS is challenging mainly due to lack of awareness and existence of 'stroke mimics' resulting in delay in AIS diagnosis. Contrary to adults who have significant pre hospital delays, children have marked in-hospital delays in AIS diagnosis (mainly in obtaining assessments and confirmatory diagnostic imaging). In children with AIS, studies report overall delay in AIS diagnosis from symptom onset ranging from 16 - 24.8 hours and in-hospital delays ranging from 9.6 -12.7 hours [94-97]. In one recent study of 209 children with acute AIS, although 58% of children reached hospital within 3 hours and another 12% within 3-6 hours, only 20% of children were diagnosed with stroke within 6 hours of symptom onset (10% within 3 hours). In children that had their symptom onset outside the hospital, the median interval from onset of symptoms to hospital arrival was 1.7 hours and from hospital arrival to initial neuroimaging was 3.1 hours and the AIS diagnosis was 12.9 hours (range 5 -31.1 hours) [96]. In this study, the total median delay was 29-hours (range 11.3 -65.9 hours). Additionally, ischemic stroke was not clinically suspected in over 62% of these children at initial presentation. This data indicate that much needs to be done to overcome the existing delays in pediatric stroke diagnosis. Prompt and correct etiological diagnosis in children with ischemic stroke is necessary not only for the appropriate and timely hyperacute therapeutic intervention but also for the prediction of recovery from stroke and the stroke recurrence rate [24, 25, 98].

Acute Antithrombotic Therapy

During the acute treatment phase, if not enrolled in the t-PA trials, treatment with an antithrombotic (either anticoagulant or antiplatelet) therapy is advised (a 2C or class I recommendation with level of evidence A). This recommendation is based on the adult literature and few pediatric case studies that have demonstrated both the safety and the efficacy of antithrombotic treatment in children with AIS [99-107]. A single prospective study compared the effects of Aspirin to low molecular weight heparin in 135 children with AIS and found no statistically significant differences in the two treatment groups Strater [107]. A very recent study by Schechter and colleagues [108] retrospectively assessed safety of anticoagulation among 215 children with AIS. In their study, 123 children received anticoagulants within 7 days of AIS diagnosis. The rate of new or increased intracerebral hemorrhage was 11% (symptomatic 4%, asymptomatic 7%) in children treated with anticoagulant therapy and 16% in the non-anticoagulant treated group. The hemorrhages were mild in all children treated with anticoagulant therapy, except in one child and all hemorrhages occurred within one month of the initiation of anticoagulant therapy [108].

However, lack of randomized controlled studies regarding the choice of antithrombotic agents (antiplatelets versus anticoagulants) in children with AIS has generated much controversy. This controversy is evident in the two simultaneously published guidelines outlining the management of ischemic stroke in children, the United Kingdom Royal College of physicians Pediatric Stroke Working group (UK) and the American College of Chest Physicians (ACCP) practice guidelines (this guideline was updated in year 2008). Both

guidelines were consensus or working group recommendations among physicians with expertise in pediatric stroke (including neurologists, hematologists, neurosurgeons and physiatrists and rehabilitation therapists). [44, 68-70, 109]. Subsequent to these two guidelines, American Heart Association (AHA) guidelines and the Canadian Medical Association (CMA) best practice recommendations were published for the management of stroke in infants and children. The AHA and ACCP guidelines had similar recommendations for the acute and preventative treatment of AIS in children [44, 109]. Both recommended acute treatment with anticoagulation (within 12-hours – 24 hours of stroke symptoms onset) until cardioembolic and craniocervical dissection etiologies are ruled out. However differences existed in the duration of anticoagulant therapy. According to the ACCP guideline, for children with confirmed AIS without hemorrhage, anticoagulation with standard unfractionated or low molecular weight heparin is recommended in the first 5 to 7 days until the evaluation for underlying etiologies and risk factors is completed. The dose of heparin is adjusted based on the serum anti Xa activity (with target anti Xa factor levels of 0.5-1.0 U/ml for standard unfractionated heparin and 0.35-0.7 U/ml for low molecular weight heparin). In situations where the coagulation system plays a major role, such as cardioembolic stroke, arterial dissection and prothrombotic states, children are advised to be continued on either oral (preferably warfarin with target therapeutic INR of 2.0-3.0) or subcutaneous anticoagulants for 3-6 months and then switched to an antiplatelet agent, usually aspirin. AHA recommended that continued treatment with anticoagulation is advised for at least six weeks or until cerebral arterial abnormalities resolve/improve or underlying heart defect is corrected, followed by switch to antiplatelet therapy. The UK guidelines had different recommendations and advised antiplatelet therapy with aspirin (3 – 5 mgs/kg/day) for both initial acute and preventative treatment of AIS in children [70]. However, they advised that anticoagulation may be considered and discussed with the senior pediatric cardiologist and hematologist for cardioembolic stroke and with pediatric hematologist for children with extracranial cervical dissection (without hemorrhage) and prothrombotic states [70]. The CMA best practice recommendations have primarily endorsed the AHA guidelines [68].

These guidelines clearly indicated the urgent need for systematic randomized studies for the treatment of children with AIS. Efforts are now underway among the international pediatric stroke network investigators to address these important questions and controversies.

Supportive Therapy

In children with AIS, until more research has been undertaken regarding efficacy and safety of various potential therapies that may be used during the hyperacute period, the general supportive measures are the mainstay in the management of these children.

The general supportive measures are aimed at decreasing the volume of infarction by salvaging the brain tissue that is at risk of permanent infarction (known as the penumbra). These recommendations are most comprehensively addressed by the AHA guidelines and include maintenance of adequate cerebral oxygenation and blood flow, peripheral hemodynamic stability by adequate hydration and avoidance of fluctuations in blood pressures, maintenance of normoglycemic states, prompt and aggressive treatment of seizures and fever (class I recommendation, level of evidence C), and prevention and treatment of raised intracranial pressure, such as decompressive hemicraniectomy for malignant hemispheric stroke, (class IIa recommendation, level of evidence B) [14, 44, 68].

Long Term Therapy

Long term or chronic therapy is aimed at prevention of recurrent stroke, stabilization and management of underlying etiologic disorder (if known) and stroke rehabilitation.

Secondary Prevention

The risk of recurrence for childhood AIS is as high as 15% -35 [11, 24, 25, 110-112]. After the initial acute phase, treatment is therefore targeted to the prevention of stroke in children. The secondary prevention therapies for adult AIS has been shown to significantly reduce risk of recurrence and hence improve outcome [113]. However, as for acute therapy, there is no evidence for secondary prevention in children with AIS. The preventative treatment approaches are again based on adult safety and efficacy data and the recently published pediatric stroke management. All the guidelines recommend secondary prevention with an antiplatelet agent in pediatric patients with AIS, except in children that have high risk for recurrent thromboembolism. These exceptions included certain cardioembolic conditions (usually until the defect is corrected), selected prothrombotic states, and conditions associated with recurrent and multiple thromboembolic events. In these high risk children, antithrombotic therapy with anticoagulants is advised (as described for the acute treatment phase). In children, the usual recommended antiplatelet agent is aspirin, at a dose of 3-5mg/kg/day, given in once a day dose. For children that have demonstrable resistance to aspirin, treatment with another antiplatelet agent is advised, such as clopidogrel [44]. Additionally, in children that have failed aspirin or have recurrent strokes on aspirin, a switch to anticoagulation was considered by UK [70] and either anticoagulation or another antiplatelet agent by ACCP [109]. This issue was not specifically addressed by the AHA guidelines [44].

It should be noted that the above recommendations only apply to childhood AIS beyond the neonatal age group. In children with ischemic perinatal stroke, the almost negligible risk of stroke recurrence and lack of safety data does not justify treatment with thrombolytic or antithrombotic agents. The decision to treat selected neonates with antithrombotic therapy under some circumstances is rare and dependent on the underlying condition and risk of recurrent thromboembolism. These treatment considerations should always be reviewed carefully with all treating physicians and the parents/caregivers.

Rehabilitative Approaches

As in adults, traditional rehabilitative therapies are generally considered to be beneficial in children with stroke in enhancing recovery and improving function, perhaps more effective in children owing to the amazing brain plasticity at this young age. In spite of the paucity of systemic studies for these rehabilitative approaches, there is general consensus that during the acute stroke phase, these assessments should be obtained to determine need for both acute and long term rehabilitative services including: physiotherapy, occupational therapy, swallowing assessment and speech and language therapy (if required) [44, 68, 70]. In children that have suffered stroke, psychological and cognitive assessments and processes to support their adequate placement or settlement in the school (development of an individual education plan, educational assistance, etc.) and the community are other important factors to consider in this regard. There are other non-traditional therapies that, either alone or in combination,

appear to have the potential to enhance motor outcome even years after the initial stroke. These include constraint induced therapy, transcranial magnetic stimulation and conductive motor learning [114-122]. To date, two randomized controlled studies have been performed with constraint induced therapy in children with hemiplegic cerebral palsy [114, 118, 120], and one with transcranial magnetic stimulation in children with AIS [123]. These studies have shown promising results and are further explored either alone or in combination for clinical application. In addition, tendon lengthening procedures and local Botulinum toxin A injections for spasticity have shown to improve functional outcome in children with hemiplegic cerebral palsy, when paired with other rehabilitative therapies [124-126].

Treatment of Specific Etiological Disorders Associated with Ischemic Stroke

In this section the clinical management of some specific childhood disorders and etiological conditions associated with stroke are discussed.

In children with cardioembolic disorders, if possible, immediate correction of the underlying congenital or acquired defect is advised. Similarly, for cardiac valvular disease, valve repair or replacement is indicated. For patients with atrial growth such as myxoma, removal of the tumor is urgently advised. Children with severe cardiomyopathies and poor ejection fraction may require cardiac transplantation [44].

Children with evidence of active infection will require treatment with appropriate antimicrobial or antiviral therapy whereas children with stroke due to either diffuse multisystem vasculitis or primary angitis of the central nervous system require immunosuppressant treatments such as systemic steroids, cyclophosphamide or azathioprine [44].

Based on the landmark randomized trial in children with sickle cell disease (SCD), the Stroke Prevention Trial in Sickle Cell Anemia (STOP), optimal hydration, periodic transfusions to reduce sickle hemoglobin and monitoring with transcranial doppler (TCD) study is recommended [44, 70, 109, 127]. The STOP study compared periodic blood transfusions to standard care in children ages 2 to 16 years that were identified to be at high risk of stroke with TCD monitoring [128]. The STOP trial found that the reduction of sickle hemoglobin to less than 30% reduces the risk of stroke from 10% to 1% per year. In all children with SCD (with or without stroke), annual monitoring with TCD is recommended for all normal studies, in 3-6 months for mildly abnormal studies and in one month for all significantly abnormal studies (Class IIa recommendation, Level of Evidence B). In children with at least two abnormal TCD studies, periodic transfusion to reduce sickle hemoglobin are recommended (Class I recommendation, level of evidence A). In children with sickle cell disease (SCD) and stroke due to sickle cell crisis, the recommendations are: 1) Optimal hydration with intravenous fluids and correction of hypoxemia and hypotension (Class I, level of evidence C), 2) Exchange transfusion with an aim to keep sickle hemoglobin (HbSS) less than 30% and hemoglobin between 10-12.5 g/dL (Class IIa, level of evidence C), 3) After the initial exchange transfusion, long term periodic blood transfusions to reduce sickle hemoglobin (Class I, level of evidence B) [44, 70, 109]. The guidelines also recommend considerations for hydroxyurea and bone marrow transplantation for children refractory to above therapies. The preventative treatment of SCD patients with stroke due to vasculopathy has not been systematically studied. In these children, as in other stroke cases due to an

arteriopathy, antiplatelet therapy may be beneficial for secondary prevention. In addition, revascularization surgery (especially in patients with secondary moyamoya) may be considered in refractory cases [44].

In children with moyamoya disease and syndrome, special precautions are advised to avoid alterations in cerebral blood flow and cerebral vasoconstriction such as maintenance of arterial PCO₂ over 25mmHG during situations requiring general anesthesia, avoiding prolonged hyperextension of neck and maintaining stable mean arterial pressures (Class IIb, Level of Evidence C) [44]. Revascularization surgery via either indirect method such as encephaloduroarteriosynangiosis (EDAS) or pial synangiosis or direct method such as superficial temporal artery to middle cerebral artery by-pass should be considered in all patients with moyamoya (Class I, Level of Evidence B). Due to the presence of small arterial vasculature in young children, indirect methods are the preferred revascularization procedures in children with moyamoya. For both symptomatic and asymptomatic moyamoya patients, with or without revascularization surgery, preventative therapy with antiplatelet therapy is advised, except in patients with recent hemorrhage or bleeding tendencies (Class IIb, Level of Evidence C) [44].

In children with a genetic disorder, efforts should be made to treat the underlying biochemical defect (Class I, Level of Evidence B). For example, in patients with hyperhomocysteinemia, cofactor therapy with vitamin B12, folic acid and vitamin B6 is advised and in patients with Fabry disease, enzyme replacement therapy is now available and should be considered in children with recurrent stroke [44].

RECOVERY AND OUTCOME

In children with AIS, permanent motor or cognitive disabilities are observed in at least 60% to 75% of stroke survivors [16, 129-131]. Hemiparesis is the most commonly reported residual neurological deficit and is present in at least 60% of children. Other long term neurological deficits include bilateral or other motor difficulties in 11% , cognitive and behavioral deficits in 11% and speech and language difficulties in 22% of children with AIS [132]. Cognitive, memory and behavioral deficits, although commonly reported in young children, may not be as disabling at younger ages and only become apparent later [133-135]. Additional long term sequelae that can be quite disabling include structural epilepsy, movement disorders and headache. These are observed in about 15%-30% of children with AIS [6, 17, 132, 136, 137]. These permanent long term deficits significantly contribute in reducing the quality of life in survivors of childhood AIS, which also affects the entire family dynamics and the community at large [110, 138]. Mortality from stroke is reported to occur in 5%–28% [111, 130, 132]. In childhood AIS, death is mostly due to large hemispheric stroke with massive cerebral edema resulting in transtentorial or posterior fossa herniation.

The indicators of poor motor and cognitive outcome in children with AIS include young age at the time of stroke (< 12 months), alteration in consciousness and/or seizures at presentation, cortical middle cerebral artery territory infarction (especially large infarcts that occupy >10% of intracranial volume), internal capsule infarction and the presence of certain prothrombotic abnormalities [57, 111, 139]. In addition, in children the AIS outcome is also dependent on the associated etiopathogenetic conditions and co morbid disorders [25, 39,

140]. However, it is generally believed that children with brain injury have comparatively better outcomes than adults, mainly due to brain plasticity and ability of the cortex to functionally reorganize at this young age.

Recurrent ischemic events are reported in 20%-37% of children with AIS, with the highest risk reported in the first year after initial stroke [5, 25, 39, 112, 132, 141]. It should be noted that the secondary prevention strategies used in these studies varied widely and may have included children that may not have received any prophylaxis, especially in older studies. If no prophylactic therapy is received, the rate of recurrent ischemic events may be as high as 50% [112]. The factors associated with increased recurrent rates include arteriopathies with persistent vascular abnormalities [25, 39, 140, 141], presence of certain hypercoagulable states (such as MTHFR T677T, elevated Lp(a), hyperhomocysteinemia, protein C deficiency and prothrombin gene mutation) [98, 142] and coexistence of multiple risk factors in the same individual child [25, 112].

CEREBRAL SINOVENOUS THROMBOSIS

Cerebral sinovenous thrombosis is characterized by the presence of thrombus or flow interruption within the cerebral dural venous sinuses or veins which may or may not be associated with ischemic or hemorrhagic infarction. The thrombosis may involve the superficial venous system (the superior sagittal sinus and the lateral sinus), deep venous system (the internal cerebral veins, vein of Galen, and the straight sinus), or both deep and superficial systems.

In comparison to arterial ischemic stroke, cerebral sinovenous thrombosis is an uncommon form of stroke, representing 0.5% to 1% of all strokes. In adults, the incidence of CSVT has not been reported among any population studies. The data is limited to few cohort studies and stroke registries that included CSVT patients. The largest cohort study is the International Study on Cerebral Venous and Dural Sinuses Thrombosis [ISCVT], which demonstrated that 487 (78%) of 624 CSVT cases occurred in patients younger than 50 years of age. The Mexican stroke registry noted that 3% of all stroke cases were CSVT. A clinic-based stroke registry in Iran reported an annual CSVT incidence of 12.3 per million [143]. In children, the CSVT literature includes single case reports and series and a single landmark population based study, the Canadian Pediatric Ischemic Stroke Registry (CPISR) [144-149]. In the CPISR, the incidence of CSVT was estimated as 0.67 per 100,000 children per year in Canada. The CPISR studied 160 children (newborn - 18 years of age) with clinical symptoms and radiographic confirmation of cerebral sinovenous thrombosis and noted that over 40% of the CSVT cases occurred during the neonatal period (0-28 days of life). Over 55% of children presented without ischemic infarction and in 28% hemorrhage, parenchymal and or intraventricular was present in children with CSVT [144].

CLINICAL PRESENTATION

The clinical presentation of CSVT in children includes headache, altered level of consciousness, seizures, irritability and focal neurological deficits. As in adults, the degree

and type of neurological dysfunction in CSVT is related to the location of thrombosis and the presence of hemorrhage or ischemic infarction and an increase in intracranial pressure due to impaired venous drainage. Often at the time of initial presentation or with progression of CSVT, patients show clinical findings pertaining to both infarction and raised intracranial pressure. Common symptoms for CSVT in children in decreasing order of frequency included seizures in 58%, decreased level of consciousness in 44%, focal neurological deficits in 42%, headache due to increase in intracranial pressure in 34% (59% of non-neonates), and irritability/jitteriness in 17% (mainly infants) [144]. Headache in CSVT is described as diffuse and progresses in severity. In older children, the different types of headaches include the thunderclap headache (indicative of subarachnoid hemorrhage), migrainous headache, and isolated non-specific headache without focal neurological findings or papilledema. Older children that present with the typical symptoms of headache, papilledema, and or diplopia (caused by sixth nerve palsy) due intracranial hypertension, even without other neurological focal signs, should be probed for the CSVT diagnosis.

With the regards to the location of thrombosis, the Canadian Registry notes that 86% of thrombosis is located in the superficial venous system and 38% in the deep venous system [144]. Thrombosis in the superior sagittal sinus commonly leads to headache, increased intracranial pressure and papilledema. Older children with bihemispheric venous infarction and or hemorrhage due to superior sagittal sinus thrombosis may present with paraparesis. In addition, other focal motor deficit, sometimes with seizures, may occur as well as scalp edema and dilated scalp veins that can be seen on examination. For lateral sinus thrombosis which is often associated with middle ear infection, symptoms such as fever, ear discharge, pain in the ear or mastoid region and headache are common. The deep cerebral venous system thrombosis results in thalamic or basal ganglia infarction. Most children with deep CSVT present with rapid neurological deterioration, mainly decreased level of consciousness. Cortical vein thrombosis although not uncommon but clinical syndromes (e.g., temporal lobe hemorrhage associated with vein of Labbe' thrombosis) associated to the larger cortical vein thrombosis are infrequently seen in children.

ETIOLOGIES AND RISK FACTORS

Various risk factors contribute to the etiology of childhood CSVT. Traditionally, etiologies for CSVT can be categorized as either 'infectious' or 'non-infectious'. The infectious CSVT, accounts for 18% of pediatric CSVT and is identified by thrombosis of venous sinuses due to infections in the head and neck or systemic infection (for example: otitis media, mastoiditis or sinusitis, sepsis). In children, infection-related CSVT is very common as oppose to adults. In comparison, the mechanism that initiates thrombosis in non-infectious CSVT has yet to be properly determined. Underlying risk factors for non-infectious CSVT can be divided into two groups. This first group being acquired risk factors which include surgery, head trauma, dehydration, congenital heart disease, chronic systemic diseases such as inflammatory bowel disease, nephrotic syndrome, Behçet disease, iron-deficiency anemia, exogenous hormones or procoagulant drugs (e.g., L- Asparaginase, oral contraceptives) or states (e.g., cancer). The correlation of cancer, commonly hematologic malignancies, to childhood CSVT has been speculated for some time. The CPISR has

reported that 8% of cases of childhood CSVT have some type of cancer. The likely mechanisms associated with cancer in children with CSVT include direct tumor compression, tumor invasion of cerebral sinuses, and the hypercoagulable states associated with cancer and chemotherapeutic and hormonal agents used for cancer treatment. Other uncommon causes that have been related with CSVT include: paroxysmal nocturnal hemoglobinuria, thrombocythemia, heparin-induced thrombocytopenia, thrombotic thrombocytopenic purpura [143]. The second is genetic risk factors or inherited thrombophilia such as deficiency of antithrombin III, protein C, and protein S; mutations in factor V Leiden, prothrombin gene and hyperhomocysteinemia [143, 144, 150-153] (Table 3).

In comparison to adults, prothrombotic disorders have been reported to occur in 20% - 80% of childhood CSVT cases. [143, 144, 151-153]. Most helpful is the recent meta-analysis by Kenet and colleagues [154] which [154] investigated both inherited and acquired thrombophilic disorders in children (0 to 18 years of age) that had suffered an initial ischemic stroke event of any type (i.e., both ischemic stroke sub-types: arterial ischemic stroke (AIS) and cerebral sinovenous thrombosis (CSVT)). Twenty-two studies met inclusion criteria, with a total 1764 patients (1526 AIS, 238 CSVT) and 2799 control subjects were enrolled. They found that for each thrombophilia trait investigated a statistically significant association with first stroke existed. In addition, they found no difference between AIS and CSVT patients. The summary odds ratios for each trait investigated included : antithrombin deficiency, 7.06 (95% CI, 2.44 to 22.42); protein C deficiency, 8.76 (95% CI, 4.53 to 16.96); protein S deficiency, 3.20 (95% CI, 1.22 to 8.40), factor V G1691A, 3.26 (95% CI, 2.59 to 4.10); factor II G20210A, 2.43 (95% CI, 1.67 to 3.51); 6.95 (95% CI, 3.67 to 13.14), and combined thrombophilias, 11.86 (95% CI, 5.93 to 23.73).

CLINICAL DIAGNOSIS

The clinical findings suggestive of CSVT and the specific imaging methods are necessary for diagnosing CSVT accurately and promptly. The slow progression and later appearance of symptoms often complicates and delays CSVT diagnosis and treatment. Presence of various risk factors and symptoms for CSVT further contribute to these challenges. Several important clinical features that contribute in identifying CSVT from other cerebrovascular abnormalities include focal or generalized seizures, changes in the level of consciousness without focal neurological findings, objective signs of raised intracranial pressure and bilateral brain involvement. In recent years, the widespread availability of neuroimaging tests, in particular magnetic resonance imaging (MRI), has allowed improved detection and diagnosis of ischemic stroke in children. The diagnosis of CSVT requires neuroimaging evidence of thrombus or lack of flow in the cerebral veins or venous sinuses either by head CT venogram (CTV) or MR venogram (MRV) with contrast (Figure 5). Head CT alone may miss the presence of infarct and/or sinus involvement. A non-contrast CT or MR venogram can often lead to the erroneous diagnosis of CSVT. A false positive result on non-contrast imaging may be due to the increased hematocrit in neonates and most commonly low blood flow in the cerebral venous system. In the CPISR, initial non-contrast head CT scan missed the diagnosis of CSVT in over 15% of patients. The characteristic findings that suggest CSVT on a non-contrast CT include 'dense triangle' or the 'cord sign' which indicates hyperdense thrombus in

the sinovenous channels. On the contrast enhanced venogram, an empty triangle or the ‘delta sign’ represents a clot in the venous sinuses. Combined with ability to detect early parenchymal lesions by diffusion weighted sequences and absent flow and presence of thrombus via venogram without radiation effects, brain MRI and MR venogram have become the diagnostic imaging modalities for CSVT at many paediatric hospitals [143].

Table 3. Etiologies and Risk factors for Cerebral Sinovenous Thrombosis in Children

Systemic Risk Factors	Prothrombotic Disorders and States
Dehydration	<i>Inherited Causes</i>
Septicemia	Protein C deficiency
Fever	Protein S deficiency
Malignancy	Activated Protein C resistance
Head and neck Disorders	Lupus anticoagulant presence
Head and neck infections(e.g., otitis media, mastoiditis, sinusitis, local abscess, meningitis)	Antiphospholipid antibodies presence
upper respiratory tract infections	Hyperhomocystenemia
Local compression of venous sinuses	Factor V Leiden mutation
Tumor invasion of venous sinuses	Prothrombin 20210A mutation
Head and neck Injury	<i>Acquired Causes</i>
Cranial Surgery	Cancer
Hematological Disorders	Procoagulant drugs (e.g., L-asparaginase, steroids)
Hemoglobinopathy (e.g., sickle cell disease)	Nephrotic syndrome
Iron deficiency anemia	Cyanotic congenital or acquired heart disease
Paroxysmal nocturnal hemoglobinuria	Autoimmune Disorders
Polycythemia	Systemic lupus erythematosus
Thrombocythemia	Sarcoidosis
Thrombotic thrombocytopenic purpura	Inflammatory bowel disease
Heparin-induced thrombocytopenia	Behçet disease
	Thyroid disorders

TREATMENT

As with AIS, the treatment of CSVT includes both general supportive measures and antithrombotic therapy. In addition, treatment of underlying etiology is extremely important such as treatment of infections and dehydration. The antithrombotic therapy is aimed at preventing the clot propagation and recurrence within the cerebral venous system. For children (outside the neonatal age group) without evidence of significant intracranial hemorrhage, both ACCP and AHA guidelines recommend treatment with anticoagulation for duration 3-6 months, with reassessment of re-canalization at 3-months. With significant intracranial hemorrhage, monitoring with serial neuroimaging is advised and in case of clot propagation in these patients, treatment with anticoagulation is advised [109, 143]. However, in neonates, there is no consensus. The ACCP guidelines recommend treatment with anticoagulation in neonates without large ischemic infarction or intracerebral hemorrhage and

radiographic monitoring for children with intracerebral hemorrhage with the recommendation to initiate anticoagulation if the extension of thrombosis occurs [109]. The AHA recommendations are to provide supportive therapy such as treatment of dehydration, infection, raised intracranial pressure and seizures. The AHA recommends that anticoagulation may be considered in selected neonates that show clinical or radiological propagation CSVT in spite of supportive therapy [143].

Figure 5. A term infant with cerebral sinovenous thrombosis who presented at the age of 20 days with decreased feeding, lethargy and generalized seizures. A) Initial CT head demonstrating evidence of poor grey and white matter differentiation, sulcal effacement and small ventricles consistent with diffuse cerebral edema and presence of hyperintensity along the falx consistent with blood in the subarachnoid space. B and C) A subsequent MRI brain showing evidence of bilateral diffusion restriction on the diffusion weighted images with corresponding apparent diffusion coefficient map consistent with bilateral paramedian frontal lobe ischemic infarction. D, E and F) The gadolinium enhanced MR venogram demonstrating presence of filling defect in the straight and the superior sagittal dural venous sinuses confirming thrombosis in these venous sinuses (arrows).

FUTURE DIRECTIONS

Research into childhood stroke is at early stages. Almost all management approaches are extrapolated from adult data. The International Pediatric Stroke Study (IPSS) (<https://app3.ccb.sickkids.ca/cstrokestudy>) and its network of investigators are making remarkable but early efforts to improve stroke care in children. Some of these great efforts includes identifying role of infection in pediatric cerebral vasculopathies and determining safety of hyperacute t-PA therapy in children (which is currently standard of care in adults). This global and multicentre participation has and will continue to facilitate systematic research in pediatric stroke thereby enhancing our overall understanding of this disabling disorder in children.

ABSTRACT

The immune system is an incredible defense mechanism which protects us against a myriad of potential pathogens like viruses, bacteria, protozoa, etc. It often shows rapid, very protective and highly specific responses. When the immune system is activated, a series of complex and inter-dependent cellular responses occur. An incredible feature of the immune system is to discriminate self from non-self. This skill of the immune system is extremely essential to destroy invading pathogens and altered cancer cells. Our first line of defense against foreign organisms are barrier tissues such as the skin that stops the entry of organisms into our body. If, however, these barriers are penetrated, the body contains cells that respond rapidly to the invaders. The cells of the immune system interact with one another by a variety of signal molecules so that a coordinated response may be mounted. These signals may be secretory molecules such as lymphokines, cytokines and chemokine's or receptors and their ligands on the cell surface which stimulate cells of the immune system. Although these two arms (innate and adaptive) of the immune system have distinct functions, there is interplay between them to influence each other. Although for many years the CNS was considered an immune-privileged organ, it is now well accepted that the immune system and the nervous system are engaged in bidirectional crosstalk. Moreover, mounting data suggests that in the brain, as in peripheral organs, inflammatory cells participate in tissue remodeling after injury. Microglial cells are the resident macrophages of the brain and play a critical role as resident immunocompetent and phagocytic cells in the CNS. Stroke is the second most common cause of death worldwide and a major cause of acquired disability in adults. Despite tremendous progress in understanding the pathophysiology of stroke, the translation of this knowledge into effective therapies has largely failed, with the

exception of thrombolysis, which only benefits a small proportion of patients. Systemic and local immune responses have important roles in causing a stroke. However, potential therapeutic targets in the immune system and inflammatory responses have not been well characterized. Development of novel and effective therapeutic strategies for a stroke will require further investigation of these pathways in terms of their temporal profile (before, during, and after the stroke) and risk-to-benefit therapeutic ratio of modulating them.

INTRODUCTION

Systemic and local immune responses have important roles in causing stroke and are implicated in the primary and secondary progression of ischemic lesions, as well as in repair, recovery, and overall outcome after a stroke. In this chapter, we will discuss the effects of innate and adaptive immune responses in the CNS and overall outcomes in patients with stroke, and discuss their contribution to stroke onset, ischemic brain damage, and recovery. We know that all cells of the immune system have their origin in the bone marrow and they include myeloid and lymphoid which differentiate along distinct pathways. The myeloid progenitor cell in the bone marrow gives rise to erythrocytes, platelets, neutrophils, monocytes/macrophages and dendritic cells (DCs), whereas the lymphoid progenitor cell gives rise to the natural killer (NK) cells, T cells and B cells. For T cell development, the precursor T cell must migrate to the thymus where they undergo differentiation into two distinct types, the CD4⁺ helper T cell and the CD8⁺ cytotoxic T cell. CD4⁺ helper T cells can be further subdivided on the basis of the cytokine profile into Th1 and Th2 cells. Th1 cells secrete mainly IL-2, IFN- γ , lymphotoxin, etc. and are responsible for cell mediated immunity. In contrast Th2 cells produce chiefly IL-4, IL-5 and IL-10 and are responsible for humoral immunity (Mossman et al. 1989). B cells originate from bone marrow in mouse, human and other mammals and from bursa of Fabricius in birds. B cells produce diverse repertoires of antibodies, synonymously called immunoglobulins (Igs).

CELLS OF THE IMMUNE SYSTEM

The immune system consists of a wide range of distinct cells, each with a specific role to play. The myeloid lineage of cells includes macrophages, dendritic cells, monocytes, mast cells and basophils. The lymphoid lineage includes NK, B cells and T cells. Some of these cells like B cells, macrophages and dendritic cells help in antigen presentation to T cells. The cells of the immune system are found in peripheral organized tissues like spleen, lymph nodes, Payer's patches of the intestine and tonsils etc.

The immune responses occur in these sites. The cells of lymphoid origin are also found in central lymphoid organs like the thymus and bone marrow where they undergo maturation. Lymphocytes and macrophages constitute a substantial portion of recirculating pool of cells found in the blood and lymph and provide immunity at the sites where it is needed. Some specialized cells like epithelial and stromal cells provide the anatomic environment in which immunity occurs by secreting many chemical factors that regulate growth and gene activation

in cells of the immune system. They also play a direct role in the induction and effector phase of the immune response.

The response to pathogens is orchestrated by the complex interactions and activities of the large number of diverse cell types involved in the immune response. The innate immune response is the first line of defense and occurs soon after pathogen exposure. It is carried out by phagocytic cells such as neutrophils and macrophages, NK cells, and granulocytes (Medzhitov et. al. 2001, 1997). The subsequent adaptive immune response includes antigen-specific defense mechanisms and may take days to develop. Cell types with critical roles in adaptive immunity are T cells and B cells.

Antigen-presenting cells (APCs) are critical players in the immune response. The function of these cells is to engulf pathogens or dying cells, process them and finally present their antigenic epitopes in context with MHC molecules to T cells. However, DCs are the only cells involved in antigen presentation to the naïve T cells. For optimum activation of naïve T cells, two signals are required. The first signal is antigen specific and is delivered through binding of the T-cell receptor (TCR) to peptide/MHC complexes on the APC surface. The second signal is non-specific and is also APC driven in the form of costimulatory molecules (Lenschow et. al. 1996). Among APCs only DCs constitutively express these costimulatory molecules. Several other cells, classified as non-professional APC, can be induced to express MHC-II molecules or costimulatory signals to work as an APC. Many of these cells like fibroblasts, astrocytes, epithelial cells, etc., function as an APC only for a short period during a sustained inflammatory response (Sung et. al. 1997, Pechhold et. al. 1997). Moreover, the main professional APCs are dendritic cells, macrophages and B cells.

Strokes are the second most common cause of death worldwide and a major cause of acquired disability in adults. Despite tremendous progress in understanding the pathophysiology of a stroke, translation of this knowledge into effective therapies has largely failed, with the exception of thrombolysis, which only benefits a small proportion of patients. Systemic and local immune responses have important roles in causing strokes and are implicated in the primary and secondary progression of ischemic lesions, as well as in repair, recovery, and overall outcome after a stroke. However, potential therapeutic targets in the immune system and inflammatory responses have not been well characterized. Development of novel and effective therapeutic strategies for strokes will require further investigation of these pathways in terms of their temporal profile (before, during, and after the stroke) and risk-to-benefit therapeutic ratio of modulating them.

Worldwide, around 15 million people have a stroke every year, and with about 5 million deaths, strokes are the second most common cause of death and a major cause of long-term disability [AHA 2010]. It is estimated that about 25% of people older than 85 years will develop a stroke. In the past 10 years, remarkable progress in understanding stroke pathophysiology has been made, especially in ischemic stroke, which makes up 80% of all cases. These advances have led to the identification of more than 1000 molecules with brain-protective effects from experimental models and to the implementation of more than 250 clinical trials. Despite all these efforts, translation into effective therapies has failed. Reperfusion induced by alteplase (tissue plasminogen activator; TPA) is the only acute pharmacological treatment approved by the health authorities [Young AR 2007, NIHD 1995]. Systemic inflammation is strongly linked to the occurrence of a stroke, and inflammation might have deleterious effects during and after an event, triggering various cascades of damage. However, some recent data show that inflammatory processes might also have

beneficial effects (figure 1.1). Such inflammatory responses involve not only peripheral cells such as leukocytes, but also brain cells such as glial cells, endothelial cells, and neurons. In this chapter, we will focus on the effects of innate and adaptive immune responses in the CNS and overall outcomes in stroke patients, and discuss their contribution to stroke onset, ischemic brain damage, and recovery. We also discuss potential immune-based stroke therapies. We postulate that a better understanding of the interactions between the immune system and the CNS will foster the development of innovative therapeutic strategies for patients with stroke.

Figure 1.1. Complex interactions between peripheral inflammation (which might underlie the occurrence or atherosclerosis of a stroke), stroke-induced brain inflammation, and responses of the peripheral innate and adaptive immune systems to a stroke (inflammation, immunodepression, autoreactivity, or protective immunity).

Role of Inflammation and the Immune System in Stroke

Nearly all types of infectious agents have been suggested to increase incidence of a stroke. However, the risk of a stroke might be associated with an aggregate burden rather than with an individual pathogen. Moreover, a range of host factors, including genetic ones, probably interact with infectious or inflammatory conditions to influence the risk of vascular disease. Inflammatory processes affect stroke incidence through several mechanisms, including thrombosis through the coagulation system, vasculopathy through vasculitis or altered vascular reactivity, and, most often, by atherosclerosis (figure 1.2). The prothrombotic state reported during inflammation results from the activation of many cellular targets (e. g, monocytes, macrophages, platelets, endothelial cells, and T lymphocytes), leading to an imbalance between anticoagulant and procoagulant molecules, an increased production of chemokine's such as monocyte chemoattractant protein-1), cytokines (interleukin 1 β , 4, 6, and 10, tumor necrosis factor [TNF], interferon's and an altered production of adhesion molecules (P-selectin, E-selectin, L-selectin, vascular cell adhesion molecule 1 [VCAM1], intercellular adhesion molecule 1 [ICAM1], and integrin's such as CD11a-c). Circulating cells are thus recruited to the endothelial wall and promote local inflammatory events. Besides vasculitis, inflammation can also induce various processes in the cerebral microvasculature, such as blood-brain barrier leakage (partly mediated by matrix metalloproteinase [MMPs]), sequestration or adhesion of red blood cells on endothelial cells (leading to apoptosis of the latter), and platelet activation or aggregation. Among the recruited leukocytes, neutrophils, natural killer cells, dendritic cells, and macrophages produce mediators that further activate or even damage endothelial cells through activation of nitric oxide synthase (iNOS) and cyclooxygenase-2 (COX-2) pathways. Together, these events favor a T-helper-type-1 (Th1) environment for infiltrating T lymphocytes and induce their activation. Conversely, some experimental studies suggest that preinfections might have a protective role by increasing neurogenesis, promoting anti-inflammatory responses, inhibiting macrophage and T-cell accumulation within atherosclerotic lesions, and producing neuroprotective molecules and free radical scavengers, leading to a form of preconditioning. However, the consensus at present is that the cumulative effect of previous inflammation on stroke incidence is negative and suggests that inflammation is an important therapeutic target for stroke prevention. Thromboembolism is the most common mechanism of cerebrovascular occlusion, but a stroke can also manifest as a complication of systemic inflammatory disorders or autoimmune processes such as inflammatory bowel disease, primary or secondary vasculitis, rheumatoid arthritis, or antiphospholipid syndrome [Deb P 2010]. Compelling evidence links inflammation (acute or chronic) and risk of a stroke to systemic infection; for example, about 30% of patients with ischemic stroke present with a recent antecedent infection and stroke incidence increases with epidemics such as influenza pandemics.

Immune System-Brain Interactions in the Acute Phase of a Stroke

An ischemic stroke results in an abrupt deprivation of nutrient supplies that quickly leads to irreversible damage in the core of the affected area. Secondary processes, such as the partly excitotoxicity, oxidative stress, and mitochondrial disturbances, spread cellular damage into preserving peri-infarct area (penumbra). Ischemic reperfusion injury also induces a robust

inflammatory response that might be necessary for tissue repair and regeneration in advanced stages. Minutes to hours after onset of cerebral ischemia, a cascade of inflammatory events is initiated through the activation of resident cells (including microglia) and recruitment of circulating leukocytes. Primary signals that trigger upregulation of inflammatory mediators are endogenous molecules (damage-associated molecular patterns [DAMPs]) released from dying cells, such as high-mobility group box 1 (HMGB1), hyaluronan, or heat shock proteins [Chen GY 2010]. Many DAMPs are sensed by Toll-like receptors (TLRs), a receptor family with broad cellular expression originally described as microbial sensors of the innate immune system.

Studies of TLR-2-deficient or TLR-4-deficient mice reported that these TLRs have a harmful effect through increasing stroke-induced lesions and inflammation. Recently, a study [Lahnardt S 2010] showed that TLR-2 and TLR-1 require the recruitment of CD36 as a co-receptor to promote the inflammatory responses and tissue damage evoked by cerebral ischemia in rodents. TLR-2 may also be a therapeutic target to prevent atherosclerosis, since these receptors mediated inflammation in an in-vitro model of human atherosclerosis [Monaco C 2009]. However, agonists of TLR can induce protective preconditioning [Marsh BJ 2010, Leung PY 2010]. Among the most studied DAMPs is HMGB1—a ligand of TLR-2, TLR-4, and advanced glycation end product (RAGE) —which is released by damaged cells and exerts a deleterious proinflammatory effect in ischemic rodents. However, HMGB1 could have a biphasic action, with an acute inflammatory noxious effect on the early stage, followed by a promotion of repair processes later on, including neurogenesis and angiogenesis; this delayed beneficial response is associated with HMGB1-positive reactive astrocytes [Hayakawa K 2010a and 2010b]. Strategies that interfere with DAMP-receptor pathways might be a promising approach to restrict inflammation processes. Downstream of DAMP-receptor signaling, inflammatory mediators such as cytokines (interleukin-1 β , TNF, and interleukin-6), chemokines, nitric oxide, and reactive oxygen species are released, exacerbating cell death and eventually leading to dysfunction of the blood–brain barrier. Cytokines and chemokines induce upregulation of adhesion molecules, including P-selectin, E-selectin, and ICAM1 on the vascular endothelium, attracting and homing circulating leukocytes into the cerebral parenchyma.

Immune system preserves tissue homeostasis of the host when threatened by a pathogen or sterile injury (e.g., ischemia) via two mechanisms: innate (non-specific) immunity and adaptive immunity. An immune response that begins immediately after injury or infection and relies on various cell types including polynuclear cells, macrophages, and dendritic cells, as well as resident cells from tissue lesions such as endothelial cells or microglia. These cells recognize danger signals (damage-associated molecular patterns [DAMPs]) released upon tissue injury. Engagement of broad-specificity receptors such as Toll-like receptors by DAMPs triggers an inflammatory response marked by the release of proinflammatory cytokines and chemokines and recruitment of innate immune cells. An antigen-specific immune response depends on lymphocytes that have antigen-specific receptors. Unlike innate immunity, cells of adaptive immunity develop memory against the stimulating antigen. Full activation of immune cells needs two signals the main TCR signal and the other costimulatory signal. Responses are regulated by several subsets of CD4 T-helper (Th) cells characterized by their cytokine secretion. Th1 cells produce interferon- γ , which is involved in macrophage activation and leads to cell-mediated immunity, whereas Th2 cells release interleukin-4, which stimulates the production of antibodies by B cells. Interleukin-17-

producing T cells (Th17 cells) are a newly described subset implicated in the inflammatory response. The simplistic view of Th1–Th2 dichotomy is far from the true complexity in human diseases because Th polarization is relatively easy to define in murine models, whereas clear distinctions between the patterns are more difficult to establish in human beings. Innate T cells with a T-cell receptor that is distinct from that of conventional $\alpha\beta$ T cells. $\gamma\delta$ T cells do not recognize antigens displayed on MHC molecules, but rather recognize specific ligands expressed on stressed or infected cells but not healthy cells.

A physiological process that aims to limit tissue damage or infection, removes dead cells and debris, and promotes tissue remodeling and regeneration (irrespective of the initiating stimulus). However, inflammation might have adverse effects through collateral cellular damage, in particular in the brain parenchyma after a stroke. Some cells in the nervous system express MHC molecules and can thus act as antigen-presenting cells to regulate T cells. Notably, neurons that do not express MHC molecules can control the function of T cells.

Natural Regulatory T Cells

These cells express CD4, CD25, and the transcription factor forkhead box P3 (Foxp3) and are involved in the maintenance of peripheral tolerance. These cells act by cell-to-cell contact and by the release of immunosuppressive cytokines such as interleukin-10 or transforming growth factor- β . Other subsets of regulatory cells have also been described (e.g., CD8 T cells, B cells, or myeloid-derived suppressive cells). A peripheral tolerance mechanism induced by exposure to antigens at mucosal surfaces. The kinetics of recruitment of the different inflammatory cells are under debate, but it is accepted that neutrophils lead the migration into the brain parenchyma, followed by macrophages and lymphocytes a few days after injuring [Jin R 2010]. Additionally, dendritic cells might accumulate, but the role of these key inflammatory cells in ischemic remains to be established [Gelderblom M 2009]. The lymphocytes have a crucial function in inflammatory processes and are strongly associated with deleterious effects in strokes, as noted in T-cell and B-cell deficient mice, which have a strikingly reduced infarct size after transient focal ischemia [Hurn PD 2007]. Administration of the immunosuppressive drug fingolimod, which, among other effects, inhibits T-cell infiltration into inflammatory tissues, also reduced infarct volumes in a mouse model of ischemia [Schichita T 2009]. Progress has been made in understanding the role of different T-cell subsets in ischemic inflammation [Lo EH 2009]. Shichita and colleagues [Schichita T 2009] reported that a late infiltration of $\gamma\delta$ T cells was associated with the neurological injury. Their experiments with interleukin-17 or interleukin-23 knockout mice show that interleukin-17 produced by these $\gamma\delta$ T cells was involved in the pathogenic mechanism and its expression was dependent on interleukin-23, which is a cytokine mainly secreted by blood-derived macrophages when they infiltrate the brain. In mice, depletion of CD4/CD25/FOXP3-positive regulatory T cells with a specific anti-CD25 monoclonal antibody increases the size of the ischemic lesion and upregulates proinflammatory cytokines such as TNF, interleukin-1 β , and interferon. The neuroprotective effects of regulatory T cells were mediated by interleukin-10. Conversely, Ren and colleagues [Ren X 2010] could not confirm that regulatory T cells were involved in restricting the area of brain ischemic injury. Hence, the role of regulatory T cells in a stroke needs to be clarified. Besides infiltrating leukocytes, neurons, astrocytes, and microglia also participate in ischemic brain injury,

through the release of proinflammatory mediators [McCoy 2008, Didier N 2003, Hayakawa K 2008]. Under inflammatory conditions, however, activated microglia can convert to a macrophagic phenotype and thus also exert a neuroprotective info once by phagocytosis of necrotic cells and secretion of neurotrophic factors such as brain-derived neutrophic factor or insulin-like growth factor [Thored P 2009, Dennes A 2007]

Figure 1.2. Inflammatory mechanisms before and after a stroke. (A) Inflammatory mechanisms that promote strokes: infection and inflammatory disorders can contribute to trigger cerebral ischaemia through pathophysiological processes such as vasculitis, changes of vascular reactivity, and especially atherosclerosis. (B) The acute phase of inflammation after a stroke: ischemia causes cell death in the brain parenchyma and subsequent release of endogenous molecules termed damage-associated molecular patterns (DAMPs) from dying cells. DAMPs trigger a cascade of inflammatory events that contribute to the activation of resident cells (microglia and astrocytes) and recruitment of circulating leukocytes (neutrophils, macrophages, dendritic cells, and T lymphocytes). Production of inflammatory mediators exacerbates neuronal injury. Conversely, activated resident cells might produce trophic factors that promote tissue repair and recovery. A potential role of regulatory T cells in restricting brain ischemic injury has been proposed [Liesz A et al. 2009].

Many studies suggest that inflammation has a deleterious effect [Fessbender K 1994, Hugs PM 2002] that amplifies ischemic injury and hence is a potential target for neuroprotective treatments to prevent cell death in the penumbra. However, some evidence suggests that inflammation is also involved in recovery and repair after ischemic brain damage, [Theod P 2009, Dennes A 2007] although this notion is controversial and needs further study.

Overall, a better understanding of the specific roles of inflammatory cells is needed, in particular about the kinetics of their recruitment and their relative contributions to each step of a stroke. Notably, the emerging and the intriguing role of different T-cell subsets needs to be established. Such information would help to define the therapeutic window in which the potential beneficial effects of inflammation in brain recovery in advanced stages of ischemia could be preserved (figure 1.2).

CNS and the immune system after a stroke Nervous and immune systems engage in a bidirectional communication that aims to maintain homeostasis in the whole organism. A stroke (as any acute lesion of the CNS) can disturb this generally well balanced interaction. Briefly, ischemic brain tissue releases factors such as cytokines and neurotransmitters that can reach chemosensitive brain areas involved in immune control such as the hypothalamus, [Meisel C 2005, Chomorro A and Dirnagl U 2007, Becker KJ and Emsley HC 2010] where they can in turn activate, for instance, the sympathetic nervous system. Damage to cortical regions involved in immune regulation, such as the insula, can lead to loss of tonic inhibition and thus activation of hypothalamic areas. Furthermore, inflammatory mediators can be released from the damaged brain tissue and enter the systemic circulation where they act on cells of the immune system in the blood and secondary lymphatic organs or, through the bloodstream, activate the brain via consensus. Besides immunomodulatory signalling specific to a brain lesion, [Catania A 2009] strokes are a strong unspecific stressor (eg, sudden loss of relevant bodily functions, fear, or sense of emergency) which activate immunomodulatory systems such as the hypothalamic–pituitary axis and the sympathetic nervous system [Elenkov IJ 2006] Within a few hours after the onset of cerebral ischemia, brain–immune system interactions can result in a downregulation of systemic immunity termed stroke-induced immunodepression (SIDS). Almost all immune cells have numerous noradrenaline receptors, which can be activated by circulating epinephrine produced by the adrenal medulla or via the dense innervation by postganglionic sympathetic fibers of lymphoid organs. Noradrenaline stimulates interleukin-10 production by blood monocytes. Overall, noradrenaline decreases the number and the activity of immune cells through its pleiotropic effects. Glucocorticoids, which are produced as a result of stress induced stimulation of the hypothalamic–pituitary-axis, are also well known immunosuppressants. After a stroke, patients often have impairments in swallowing and are therefore at high risk of aspiration. They are also exposed to the challenging microbial environment of intensive care. Infections are the most prevalent and relevant complications after a stroke: pneumonia is the main cause of death in such patients [Henon H, 1979] and has a substantial negative effect on recovery and rehabilitation. Since its description on clinical strokes, [CzlonKowska A 1979] many studies have confirmed the existence of SIDS in experimental [Prass K 2003] and clinical [Vogelgesang A 2008] strokes and shown a strong correlation between immunodepression, sympathetic nervous system activation, and outcome [Chammorro A 2007]. For example, concentrations of metanephrine in the blood are as robust for prediction of clinical outcome as they are for stroke severity, [Klehmet J 2009] and markers of SIDS, such as decreased

expression of HLA-DR on monocytes, predict risk of infection [Harms H 2008]. Nonetheless, immunodepression after a stroke might also have an adaptive component. As the result of a stroke, the blood–brain barrier is disrupted; CNS-specific antigens are exposed to the immune system and may enter the systemic circulation. Downregulation of the immune system could help prevent aggressive responses. Although the general response to a stroke could be a decrease in the number of immune cells and subsequently of their function, further complexity ensues as some immune-cell subtypes could increase (e.g., regulatory T cells). Little is known about the consequences of these changes in circulating immune cells in the brain, but there are indications that they might be involved in brain protection and repair [Gee JM 2007]. Immune responses against antigens are determined by the microenvironment of the tissue in which they occur. Co-stimulatory molecules are necessary for the priming of immune responses. Such molecules are weakly expressed in the healthy brain, but become upregulated after brain damage such as a stroke. Furthermore, systemic infection, which often occurs in patients after a stroke, leads to upregulation of co-stimulatory and MHC class I and II molecules in the periphery and the brain, thus facilitating activation of T cells and B cells against endogenous brain antigens [Becker KJ 2009]. As a result of systemic inflammation, for example, during infection cytokines are produced outside and within the brain and mediate aspects of sickness behavior [Dantzer R 2008]. Infection after a stroke might thus lead to an exacerbated proinflammatory phenotype. Within hours, a stroke induces systemic immune changes that last for weeks [Prass K 2003] and can affect clinical outcomes. SIDS at least partly explains the high risk of infection in patients after a stroke, and might thus be indirectly responsible for the production of inflammatory and co-stimulatory mediators that in turn negatively affect the brain lesion. Whether these deleterious effects of brain–immune interactions after a stroke are offset, at least partly, by their beneficial effect on brain repair or the restricted development of CNS integration is unclear.

Targets for Stroke Prevention: Role of Inflammation and Immunity

Numerous clinical trials have investigated the effects of anticoagulants (eg, low-molecular-weight heparins or warfarin), anti hypertensive molecules, antiplatelet agents (eg, aspirin, clopidogrel, Dipyridamole, ticlopidine, trifluoromethoxythienopyridine, GP IIa/IIIb inhibitors, or lotrafiban), or lipid-lowering drugs (eg, Statins) on prevention of stroke occurrence or recurrence [Stroke Trials Registry 2011]. Several of these strategies are presently being used to target the immune system. The MOSES trial, [Schrader J 2005] which tested the efficacy of an angiotensin type 1-receptor antagonist (eprosartan) versus a calcium-channel blocker (nitrendipine) in 1352 patients, showed that eprosartan reduced the risk of recurrent acute strokes by about 25%. Similarly, PROGRESS88 reported a 28% relative risk reduction (95% CI 17–38%; $p < 0.0001$) in the primary endpoint of cardiovascular events in 6105 patients who were randomly assigned to perindopril or control. Multiple trials have shown that anti-hypertensive drugs targeting the renin-angiotensin system can reduce stroke incidence. Beyond pharmacological strategies targeting this system, there are other interesting attempts to manipulate the immune system targeting molecules involved in blood-pressure regulation. PMD311789 and Cyt006-AngQb90 vaccines directed against angiotensin I and angiotensin II, respectively, have been tested in phase 2 trials and were inferior in their effect on blood pressure compared with pharmacological inhibitors of the renin-angiotensin system.

Nevertheless, strategies to improve the efficacy of such vaccines might confer substantial benefits for stroke prevention in the future by increasing the proportion of patients who are treated for hypertension, as these patients might more readily accept vaccination twice a year than pills every day. However, the long-term effects of such strategies remain unassessed [Brown MJ 2009]

Finally, because infectious agents seem to be risk factors for strokes, the argument for treating or preventing infection is well founded. For example, in one study [Hung IF 2007] dual pneumococcal and influenza vaccination was associated with a reduced number of cases of ischemic strokes than was reported in unvaccinated patients. Age dependent effects of vaccination, and the need to test, vaccination together with antiviral strategies such as use of neuraminidase inhibitors, are being discussed. Notably, prior infection has been suggested to increase hemorrhagic complications after thrombolysis with alteplase, but more data are needed [Urbanek C 2010].

Immunomodulation to Restrict Brain-Tissue Damage after a Stroke

There are strong experimental evidence which supports the role of leucocyte recruitment by adhesion molecules, cytokines, and chemokines in ischemic damage. Clinical studies support the therapeutic relevance of this pathway, and show increased ICAM1 expression in the cortex and increased circulating concentrations of soluble ICAM1 after an ischemic stroke [Rallidis LS 2009] In experimental models, co-infusion of antibodies targeting ICAM1 led to a significant improvement in neurological outcome when combined with tPA-induced thrombolysis, suggesting that ICAM1 blockade might improve functional outcome and extend the therapeutic window for thrombolysis [Bowes MP 1995]. Strategies have been designed to block the cytokine cascade that is induced after a stroke by use of recombinant human interleukin-1 receptor antagonist (interleukin-1Ra). Another promising strategy is the induction of mucosal tolerance with repeated low-dose intranasal administration of E-selectin, which causes a shift in immune responses from proinflammatory to anti-inflammatory and might even induce regulatory T cells. In rats, this immuno modulatory approach prevented ischemic and hemorrhagic strokes. The safety and effectiveness and maximal tolerable dose of E-selectin is under investigation in clinical trials [Emsley HC 2005, Takeda H 2002]

Other therapeutic approaches, such as the use of the antibiotic minocycline, showed promising results in animal models by reducing brain damage and promoting CNS repair [Tang XN 2007]. This tetracycline might exert anti-inflammatory activities through modulation of microglial activation, immune-cell activation, and thus the subsequent release of cytokines, chemokines, lipid mediators of inflammation, and MMPs [Brundula V 2002, Stirling DP 2005]. Minocycline might also reduce the harmful pro-bleeding effects of alteplase [Murata Y 2008]. Experimental evidence strongly suggests that both exogenous TPA (alteplase, injected intravenously) and endogenous TPA (produced and released by injured neurons) interact with the NR1 subunit of N-methyl-D-aspartate (NMDA) receptors, leading to increased glutamatergic signalling and subsequent promotion of excitotoxic or ischemic neuronal death. Strategies of active and passive immunization to prevent this interaction were shown to efficiently counteract the aggravating effect of TPA on excitotoxic or ischemic injuries [Macrez R 2010]. Although the translation from bench to bedside has not

been successful yet, strategies combining either anti-inflammatory drugs or neuroprotectants with thrombolytics are promising and need to be further studied.

Difficulties in Translation from Bench to Bedside and Research Priorities

With a few exceptions, positive laboratory results have not resulted in effective treatments for patients after a stroke. However, only a few trials have targeted inflammation or the immune system. What can we learn from past failures, and what are the prerequisites and prospects for future success in targeting inflammation and the immune system to prevent strokes, to minimize damage once it has occurred, and to foster regeneration and repair? First, the general question of whether the animal models of a stroke can recapitulate human pathology and predict success in clinical trials needs to be addressed. Many articles have assessed this point, [Dirnagl U 2006] which includes differences in vascular supply, kinetics of lesion evolution, confounding effects of anesthesia, difficulties in the assessment of functional outcomes, and deficiencies in the quality of preclinical trials. Accordingly, the Stroke Therapy Academic Industry Roundtable (STAIR) has provided substantial recommendations to improve the success of translation from bench to bedside. Some of these recommendations concentrate on the crucial differences between rodents and human beings and thus emphasized the need for studies into pharmacokinetics and pharmacodynamics, time to treatment, as well as inclusion of risk factors (especially ageing) and the need to use large animals [Fisher M 2005] Nonetheless, investigators need to consider specific issues about the translational roadblock when targeting immunological mechanisms. Animals used in stroke research live in conditions that are sterile or almost free of pathogens, and thus have comparatively little exposure to foreign antigens.

Moreover, rodents have a lymphatic differential blood count compared with human beings. Nevertheless, when direct comparison has been possible, it is reassuring that rodents had similar changes in adaptive and innate immunity to human beings after a stroke. However, to further improve prediction we should consider inclusion into our models of confounders related to inflammation, such as animals with atherosclerosis or pre-existing acute or chronic infections. A relevant concern relates to the potential risks involved with the use of therapeutic immunomodulation to treat strokes. Negative findings from other indications include life-threatening side-effects in a phase 1 trial of the anti-CD28 monoclonal antibody TGN1412 that was intended for the treatment of multiple sclerosis a rare but severe side-effect (progressive multifocal leucoencephalopathy) of the monoclonal antibody directed against the $\alpha 4$ subunit of integrins (natalizumab, an approved multiplesclerosis treatment), and meningoencephalitis as a side-effect of an amyloid- β vaccine in patients with Alzheimer's disease. Clearly, we need to be very alert to potential risks when targeting the immune system and carefully balance the risk-to-benefit ratios. Patients with chronic inflammatory diseases, such as rheumatoid arthritis, who might be at risk of infection or reactivation of viral infections, have successfully been treated with immunomodulatory therapies, such as rituximab, a chimeric anti-CD20 monoclonal antibody that depletes B cells. These findings prove that modulation of the immune system in elderly and severely ill patients, when done cautiously, can be safe. Another reason not to rush into clinical trials targeting the immune system in stroke patients lies in the fact that our current knowledge of the underlying pathophysiology is patchy at best. Importantly, although negative

consequences of brain inflammation after a stroke have been documented, there is some evidence that inflammatory mechanisms contribute to lesion containment or even regeneration and repair. The good and bad sides of inflammation after a stroke need to be clarified, and the differential kinetics of deleterious and potential protective or regenerative mechanisms need to be established. For example, MMPs, such as MMP-9, was reported to show deleterious effects during the stroke, but increased concentrations of these enzymes seem to promote brain recovery after a stroke. Accordingly, pharmacological approaches targeting MMPs (or any inflammatory mediator) need to be optimized for acute inhibition at the right moment (IE, to prevent damage without compromising beneficial effects). Furthermore, whether protection of one cell type necessarily protects other cell types in the neurovascular unit is not known. In this respect, it is encouraging that Dipyridamole, a platelet inhibitor used for stroke prevention, might also have anti-inflammatory and antioxidative effects, and might indirectly protect neurons through prevention of hypoxia-induced endothelial cytotoxicity. In terms of peripheral immunity in strokes, we are only beginning to understand the effects of the adaptive immune system in the pathophysiology of a stroke. Some effects, such as SIDS, which increases the risk for infection, are negative, but in other circumstances could balance, stroke-induced autoimmunity; for example, immune cells might react against brain epitopes that are normally well shielded but get exposed after a stroke. Novel investigations are needed to disentangle destruction and protection to safely and effectively modulate the immune system in patients after a stroke.

Experimental and clinical data justify cautious optimism that inflammation and immunity might one day be targeted to prevent strokes and to minimize its effects. In view of recent failures in the development of stroke treatments, the potential risks of such therapies, and the incomplete understanding of the underlying mechanisms, we advocate a cautious approach. Indeed, because of the complexities of the interactions between the immune system and the CNS during and after a stroke, it is difficult to pinpoint a mechanism as the most promising target or approach. Although immunomodulation of peripheral immune responses might carry a risk (e.g., the phase 1 clinical trial of TGN1412, which attempted to test anti-CD28 antibodies to boost regulatory T cells), we believe that such strategies could eventually lead to a viable approach to improve the stroke outcomes. Presently, clinical translation might be near for strategies that modulate innate immunity and inflammation in the brain, first through dampening deleterious hyperinflammation (classic anti-inflammation) or chronic inflammation (eg, pro-resolving drugs to overcome chronic inflammation and inflammation resolution deficits), and second by allowing inflammatory mechanisms to clear debris, restrict the spread of the lesion, and contribute signals that foster recovery and repair. Thus, a more comprehensive understanding of the endogenous immune responses, in particular with respect to different stages in the evolution of stroke pathology, from its prevention to recovery after a stroke, could help us to design safe immunomodulatory strategies with substantial benefits for patients.

Modulation of the Post-Ischemic Immune Response to Improve the Stroke Outcome

There are profound alterations in the systemic immune response following a stroke. The stroke induced changes include a dramatic increase in the systemic inflammation, as

measured by plasma concentrations of C-reactive protein (CRP) and interleukin (IL)-6 [Beamer NB 1995]. More recent data also demonstrates that a stroke leads to a sympathetically mediated dysfunction of the systemic immune response that predisposes to infection; the degree of these immunological alterations depends upon the stroke severity [Prass K 2003, Leisz A 2009]. Infection is common following a stroke, and the data demonstrate that infection in the post-stroke period, especially pneumonia (PNA), is an independent risk factor for poor outcome [Jhonston KC 1997, Aslayan S 2004, Katzan IL 2003]. Why infection predisposes towards a worse outcome is unclear, but our laboratory has focused on the possibility that an infection in this vulnerable time period may lead to changes in the microenvironment of the lymphoid organs and the brain that allow for the development of a detrimental immune response towards brain antigens. The immune response is generally thought of as having an innate, or antigen non-specific, an arm and an adaptive, or antigen specific, arm. The innate immune response is also referred to as the inflammatory response and is the first line of defense against invading pathogens and the primary response to tissue injury. It is thus not surprising that there is evidence of systemic inflammation following a stroke, and that the degree of inflammation correlates to stroke severity and ultimately to the amount of tissue infected [Adebert HJ 2004, Smith CJ 2004]. The amount of tissue infected is also reflected by the concentration of antigens like myelin basic protein (MBP), creatine kinase (CK)-BB, neuron specific enolase (NSE) and S100 in the peripheral circulation [Jauch EC 2006]. As concerns the systemic immune system, these antigens are essentially novel, which means that lymphocyte encounter with such and antigen could lead to the development of an autoimmune response. There are many potential sites of antigen encounter in the periphery, and experimental data show that antigen is present within the cervical lymph nodes shortly after the onset of a stroke [Vanzwam M 2009]. In addition, lymphocyte traffic into the infected brain tissue within days after a stroke, allowing for the possibility of novel antigen encounter within the central nervous system (CNS) itself.

For a lymphocyte to become activated to an antigen, it must generally be presented that antigen by a professional antigen presenting cell (APC) in the context of the major histocompatibility (MHC) II molecule and receive an additional costimulatory signal. The nature of the immune response is further shaped by the cytokine milieu of the environment at the site of antigen encounter. For instance, if a naïve lymphocyte recognizes its cognate antigen in the presence of interferon (IFN)- γ , a TH1 type response usually develops; if the recognition occurs in the presence of IL-4, a TH2 type response develops. Further, if antigen recognition occurs in the presence of transforming growth factor (TGF) - β 1 and IL-6, a TH17 response occurs; in the absence of IL-6, a regulatory T cell response (TREG) develops. A TREG response can also be induced in the presence of IL-10. As would be expected, the type of the effector cell/response generated after antigen encounter is associated with very different immunological outcomes. For instance, TH1 cells are associated with cellular immunity and are characterized by the secretion of IFN- γ and lymphotoxin alpha (LTA) while TH2 cells are associated with humoral immunity and the secretion of IL4, IL-5, and IL-13. And while TH17 cells play a role in host defense, they also appear to be important in the genesis of autoimmunity; TH17 cells are characterized by the secretion of IL-17 [Peck A 2008]. Inducible TREGs, on the other hand, are characterized by the secretion of TGF- β and IL-10 and, as the name implies, regulate immune responses.

To date, there has been little interest in exploring the possibility that autoimmune responses to brain might affect outcome from a stroke. There are, however, studies that

document the fact immune responses to brain antigens do occur following a stroke. For instance, lymphocytes from stroke survivors show more activity against myelin basic protein (MBP) than the lymphocytes from patients with multiple sclerosis [Younchayud U 1974]. In addition, myelin reactive T cells are found in higher numbers among patients with cerebrovascular disease [Wang WZ 1992]. These data thus provide evidence that a cellular immune response to brain antigens occurs following a stroke. Further, there are increased titers of antibodies to brain antigens, including neurofilaments and portions of N-methyl-D-aspartate receptor, following a stroke, indicating that there is also the development of a humoral response to these antigens [Bornestien NM 2001, Dambinova SA 2003]. The immune response to CNS antigens after stroke is likely just an epiphenomena of stroke, given that cerebral ischemic injury to the blood-brain barrier (BBB) allows for the systemic immune system to come into contact with the antigens that are normally sequestered from it. Nonetheless, it is possible that this response leads to “collateral damage”; whether these immune responses affect the outcomes of a stroke is a largely unanswered question. In an animal model of a stroke we have demonstrated that the predominant immune response to brain antigens, following a stroke is that of a TREG response characterized by secretion of TGF- β 1.23 Using the paradigm of mucosal tolerance, we also found it possible to induce TREG responses prior to stroke animals that exhibit a TREG response experience both better short (days) and long term (one month) outcome from a stroke [Gee JM 2008 and 2009, Zeerath D 2009]. It is thus not surprising that a recent paper found that the absence of TREG cells is associated with worse outcome from stroke [Liesz A 2009]. Induction of Treg cells characterized by the secretion of IL-10 prior to stroke also improves short term outcome and decreases infarct size. These data suggest that modulation of the post-ischemic immune response by inducing a more robust TREG response might be a viable strategy for neuroprotection. In our animal model, we also found that exposure to an inflammatory stimulus at the time of a stroke leads to a deviation of the immune response to that of a TH1 response, and the TH1 response to brain antigens is associated with worse outcome. This deviation from an endogenous TREG response to that of TH1 response induced by an inflammatory stimulus at the time of a stroke appears to be related to a change in the milieu of microenvironment at the site of antigen presentation. This observation may help to explain why persons who develop an infection in the post-stroke period have increased morbidity and mortality. It also suggests that attempts to avoid infection in the post-stroke period may be of therapeutic value. To date, however, there have only been a few trials of antibiotic prophylaxis following a stroke and these relatively small trials have conflicting results, suggesting that prophylactic antibiotic therapy may improve, worsen, or have no effect on the stroke outcome [Schwartz S 2008, Chomorro A 2005, Harms H 2008]. IL-17 was recently shown to contribute to ischemic brain injury up to 7 days after the onset of a stroke [Schichita T 2009] In this study, the IL-17 was being produced by $\gamma\delta$ T cells, which are important mediators in the antigen non-specific inflammatory response, and not by TH17 cells. Given the fact that there is robust upregulation of IL-6 following a stroke and increased expression of TGF- β 1 in brain, however, the post-ischemic cytokine milieu could favor the development of TH17 cells [Krupinski J 1996, Wang X 1995] Whether or not CNS specific TH17 cells contribute to injury in cerebral ischemia has yet to be explored, but their importance in autoimmune diseases, including experimental allergic encephalomyelitis (EAE), is clear [Furuzawa-Carballeda J 2007, Hoffstetter H 2009]. Recent data highlight the fact that the ratio of antigen specific TH17 cells to antigen specific TH1 cells as well as the cell type used

to induce EAE (TH17 versus TH1) influence both EAE phenotype and pathology [Jager A 2009, Stromnes IM 2008]. These data further suggest that the nature of the immune response to brain after a stroke has the potential to differentially affect outcome. The potential of modulating the post-ischemic immune response to improve outcome following a stroke is an intriguing neuroprotective approach as it is one of the rare interventions that could be initiated in a delayed fashion and still be expected to have an effect. There are, however, potential dangers of manipulating a response which is so complex and incompletely understood. As an example, we found that induction of MBP specific TREG cells prior to experimental strokes using the paradigm of mucosal tolerance was associated with better outcome up to one month after the ischemic injury; this benefit was not sustained to 3 months however, and there was a tendency for the animals “tolerized” to MBP exhibit a TH1 response to the antigen. Studies suggest that the phenotype of inducible TREG cells is unstable, so understanding how to prevent this “immunological drift” would be important prior to use in therapeutic trials [Zhu L 2009]. And while immunosuppressive strategies might decrease the risk of developing a TH1 (and possibly TH17?) response after a stroke, such interventions might increase the risk infection, a risk which is already high in the post-stroke period. On the other hand, strategies to enhance the immune response to prevent infection in the post-stroke period might increase the risk of developing a detrimental TH1 (and possibly TH17?) immune response to brain, and as already discussed, these responses might predispose patients to worse functional outcomes following a stroke. It is also in the realm of possibility that the development of immune responses to brain antigens, be they cellular or humoral, may have more long lasting effects. For instance, it is appreciated that a stroke is a potent risk factor for dementia, and it could be that autoimmune responses to brain contribute to cognitive decline and even the progression of white matter disease [Pendlebury ST 2009]. Future clinical studies will need to address the contribution of the post-ischemic immune response to these long-term outcomes. In summary, the nature of the post-ischemic immune response affects outcome from a stroke. Modulation of this response may be a viable approach to improving the outcome of a stroke, but there are potential dangers associated with immunomodulation. A more complete understanding of the endogenous immune response following a stroke is needed in order to safely manipulate this response in the post-stroke period.

ABSTRACT

Once considered exclusively a disorder of blood vessels, growing evidence has led to the realization that the biological processes underlying stroke are driven by the interaction of neurons, glia, vascular cells, and matrix components, which actively participate in mechanisms of tissue injury and repair. A stroke is a serious neurological disease, and constitutes a major cause of death and disability throughout the world. The pathophysiology of stroke is complex, and involves excitotoxicity mechanisms, inflammatory pathways, oxidative damage, ionic imbalances, apoptosis, angiogenesis and neuroprotection. The ultimate result of ischemic cascade initiated by acute stroke is neuronal death along with an irreversible loss of neuronal function. Therapeutic strategies for stroke have been developed with two main aims: restoration of cerebral flow and the minimization of the deleterious effects of ischemia on neurons. Intense research spanning over the last two decades has witnessed significant therapeutic advances in the form of carotid endarterectomy, thrombolytics, anticoagulant therapy, antiplatelet agents, neuroprotective agents, and treating associated risk factors such as hypertension and hyperlipidemia. However, the search for an effective neuroprotectant remains frustrating, and the current therapeutic protocols remain suboptimal. To date, only one FDA-approved drug is available for ischemic stroke; i.e., the serine protease tissue-type plasminogen activator (tPA), utility of which is limited by short therapeutic window. As new targets are identified, new opportunities emerge that build on an appreciation of acute cellular events acting in a broader context of ongoing destructive, protective, and reparative processes. The burden of disease is great, and its magnitude widens as a role

for blood vessels and stroke in vascular and nonvascular dementias becomes more clearly established. The primary objectives of this chapter are: (1) to summarize the pathophysiology of a stroke, (2) to outline the relation of Atherosclerosis with stroke and also that of inflammatory and infective conditions associated with clinical stroke, along with role of various inflammatory mediators; (3) current status and understanding the role of genetics in stroke; (4) unifying the proposed mechanisms linking various pathogenetic processes; and (5) to discuss the emerging opportunities for novel therapeutic strategies. In this chapter we will critically evaluate the major mechanisms underlying stroke pathophysiology, with emphasis on potential novel targets for designing newer therapeutic modalities.

Keywords: Ischemic stroke; Pathophysiology; Excitotoxicity; Apoptosis; Inflammation; Therapeutic targets

INTRODUCTION

Strokes are the leading cause of disability worldwide, the second most common cause of dementia and the third leading cause of death. They have enormous clinical, social, and economic implications and demand a significant effort from both basic scientists and clinicians in the quest for understanding the underlying pathogenic mechanisms, and thereby adopting suitable preventive measures and successful therapies. A stroke is a sudden loss of brain function resulting from an interference with the blood supply to the central nervous system (CNS). Normal cerebral blood flow (CBF) is approximately 50–60 ml/100g/min. The reduction in CBF below 20 ml/100g/min results in an electrical silence and less than 10 ml/100g/min causes irreversible neuronal injury (Hakim M 1998, Jones TH 1981). Lack of blood circulation to the brain deprives neurons of necessary glucose and oxygen. Neurons are the impulse transmitters; hence they require a constant supply of energy. Up to 85% of all strokes are of ischemic origin, with most attributable to blockage of one or more cerebral artery by blood clots, with resulting reduction in cerebral perfusion. The remaining stroke cases are hemorrhagic, involving either intracerebral or subarachnoid hemorrhage. Ischemic stroke may manifest in the form of thrombotic stroke (large vessel and small vessel types); embolic stroke (with/without knowing cardiac and/or arterial factor); systemic hypoperfusion (Watershed or Border Zone stroke); or venous thrombosis. Irrespective of the cause, compromised vascular supply to the brain is the primary event in majority (85–90%) of acute strokes. A lower respiratory reserve and complete dependence on aerobic metabolism make brain tissue particularly vulnerable to the effects of ischemia. A spectrum of severity is generally observed in the affected region of the brain, owing to the presence of collateral circulation. Thus, part of the brain parenchyma (core) undergoes immediate death, while others may only be partially injured with potential to recover (penumbra). Following the onset of ischemic stroke, cerebral blood flow is disrupted throughout the affected region of the brain. Blood flow disruption to the tissue is not uniform due to the presence of collateral circulation resulting in a flow gradient. Consequently, a “core” region of infarct develops in which flow is severely reduced, often approximating upwards of a 90% decrement, and tissue undergoes necrosis within minutes as insufficient adenosine triphosphate (ATP) is present to maintain homeostatic ionic gradients and metabolic functions (Astrup J 1977). Surrounding this core region in which blood flow is severely reduced is the “penumbra”, a tissue

distribution in which flow is less severely reduced and remains typically around 35% of baseline flow (Astrup J 1977). Characterized by normal cellular membrane potential but a disruption in the ability for normal action potential firing, tissue initially residing within the penumbral region progresses to cellular death, ultimately resulting in an expanded core lesion without restoration of cerebral blood flow (Lo EH 2008). As such, therapeutic development has focused on achieving reperfusion via tissue plasminogen activator (tPA) and/or restoring homeostasis via administration of ‘neuroprotective’ pharmacologic agents intended to disrupt the ischemic injury cascade.

Few neurological conditions are as complex and devastating as stroke, the second leading cause of death worldwide. Also called a brain attack, victims may suddenly experience paralysis impaired speech, or loss of vision due to interruption of blood flow (ischemia) caused by thrombosis or embolism. Less frequently (<15%), strokes are caused by hemorrhage or cardiac arrest. On average, strokes in the USA strike once every 40 seconds and cause death every 4 minutes, with an estimated 41.6% death rate in 2007 (Lloyd-Jones, 2009). With an aging population, the absolute numbers are likely to rise. Among survivors, work capacity is compromised in 70% of victims, and 30% need assistance with self-care. Hence, the disease burden is great. The estimated stroke cost was 73.7 billion dollars in 2010 (USA) and projected to be 1.52 trillion dollars in 2050 (Lloyd-Jones, 2009). No racial or ethnic groups are spared, and the problem is global. For example, in the Russian Federation and China, the estimated death rates per 100,000 populations are five to ten times higher than in the USA (Lloyd-Jones, 2009). Hence, stroke is an affliction of mankind.

Figure 1. Ischemic cascade leading to cerebral damage: Ischemic stroke leads to hypo-perfusion of a brain area that initiates a complex series of events. Excitotoxicity, oxidative stress, microvascular injury, blood-brain barrier dysfunction and post-ischemic inflammation lead ultimately to cell death of neurons, glia and endothelial cells. The degree and duration of ischemia determine the extent of cerebral damage.

MECHANISMS OF NEURONAL INJURY

Cerebral ischemia results in a number of hemodynamic, biochemical, and neurophysiology alterations (Ostrowski RP 2006). A series of complex acute, subacute and chronic events occur after the incidence of stroke and reperfusion (Jean WC 1998). Ischemic injury involves energy failure, loss of cell ion homeostasis, acidosis, increased intracellular calcium excitotoxicity, free radical-mediated toxicity, and pathological permeability of the blood-brain barrier (BBB). Free radicals, specifically reactive oxygen species (ROS) that are generated soon after ischemia, as well as in later stages of ischemic reperfusion (e.g., by inflammatory cells), are the fundamental mediators of reperfusion injury.

The development of hypoxic-ischemic neuronal injury is significantly influenced by the release of excitatory neurotransmitters, primarily glutamate and aspartate in the brain. This process is called excitotoxicity and is activated by depletion of cellular energy stores. Glutamate, normally stored inside the synaptic terminals, is released into the extracellular space in a depleted energy state, which then results in the opening of calcium channels associated with N-methyl-D aspartate (NMDA) and alpha-amino-3-hydroxy-5-methyl-4-isoxanole propionate (AMPA) receptors. This leads to an influx of calcium, sodium and chloride ions and efflux of potassium ions. (Siesjo BK 1989, Hademenos GJ 1997, Garcia JH 1994). The influx of calcium is responsible for the activation of a series of destructive enzymes such as proteases, endonucleases, and lipases that allow release of cytokines and other inflammatory mediators, resulting in the loss of cellular integrity (Siesjo BK 1981, Becker KJ 1998). Inflammatory mechanisms play an important role in tissue injury by inducing the rapid production of many different inflammatory mediators. Within 30 minutes after ischemia and reperfusion, leukocytes recruited to the ischemic area activate mediators of inflammation such as oxygen free radicals, cytokines, and nitric acid.

Ischemia causes brain damage by activating the ischemic cascade, which progresses to local depletion of oxygen or glucose, causing failure of production of high energy phosphate compounds, like adenine triphosphate (ATP). This adversely affects energy-dependent processes necessary for tissue cell survival, and sets off a series of interrelated events culminating in cellular injury and death. The extent of damage usually depends on duration, severity, and location of ischemia. Neuron, owing to its role in impulse transmission, requires a constant supply of glucose and oxygen, in order to maintain the ionic gradients across its membrane, and is most susceptible to hypoxia changes. The various mechanisms involved in tissue injury/neuroprotection are:

- Failure of mitochondria leads to depletion of cellular energy store: This causes further energy depletion and may trigger cell death due to apoptosis. Ischemia also causes loss of potassium and ATP, which are essential for energy exchange. It has been observed that energy failure do not precipitate immediate cell death, but 5–10 min of occlusion may lead to irreversible brain injury. Most of the ischemic strokes do not usually cause complete occlusion of blood supply, however even a partial occlusion for prolonged period may cause harmful effect due to deterioration of ion gradient and by-products (like lactic acid, hydrogen ions) of anaerobic metabolism (Karaszewski JM 2009).

- Loss of membrane ion pump function and its deleterious effects: Ischemia, leading to inadequate energy supply at the cellular level, leads to malfunction of ion gradient, which results in loss of potassium in exchange of sodium, chloride, and calcium ions. This is accompanied by an inflow of water, resulting in rapid swelling of neurons and glia (cytotoxic edema).
- **Release of excitatory neurotransmitters:**
 - *Glutamate:* Ischemic cascade stimulates release of excitatory neurotransmitters in the brain, viz. glutamate and aspartate. Glutamate is vital for neuronal plasticity; however an uncontrolled release in ischemic areas mediate excitotoxic synaptic transmission via activation of N-methyl-d-aspartate (NMDA), 2-amino-3-hydroxy-5-methyl-4-propionate (AMPA) or kainite receptors, which allows Na^+ and Ca^{2+} influx. This has disastrous effect on the neuronal membrane, due to: (i) utilization of already depleted ATP in maintaining calcium balance; and (ii) causing disordered activation of a wide range of enzyme systems (proteases, lipases, and nucleases). These enzymes and their metabolic products, such as oxygen free radicals, damage cell membranes, genetic material, and structural proteins in the neurons, ultimately leads to cell death (Nakanishi N 2009). Understanding of these steps has triggered a search for potential blocking agents (Brouns R 2009). Release of excitatory neurotransmitter, glutamate, to modulate activity in nearby neurons occur through six known mechanisms: (i) reversal of uptake by plasma membrane glutamate transporters (Szatkowski M 1990), (ii) anion channel opening induced by cell swelling (Kimelberg HK 1990), (iii) Ca^{2+} -dependent exocytosis (Parpura V 1994), (iv) glutamate exchange via the cystine–glutamate antiporter (Warr O 1999), (v) release through ionotropic purinergic receptors (Duan S 2003), and (vi) functional unpaired connexons, ‘hemichannels’, on the cell surface (Ye ZC 2003). Though these various mechanisms of glutamate release have been elucidated, ambiguity still persists in terms of which of these mechanisms operate during normal physiological settings and which come into play during pathological settings like ischemia or stroke, since the latter may require conditions like cell swelling or a low extracellular Ca^{2+} concentration (Malarkey EB 2008).
 - *Synaptosomal-associated protein 25 (SNAP-25):* It is a neuron-specific protein, primarily localized in nerve endings and axons and involved in synaptic vesicle exocytosis, axonal outgrowth and transmitter release. Studies have shown that SNAP-25 is differentially regulated in ischemic stroke. Marti et al. (Marti E 1998) has demonstrated an increase in SNAP-25 mRNA levels in the infarct and penumbra of stroke patients, mainly during the first 6 days after stroke. The Ca^{2+} -dependent controlled exocytosis mechanism of glutamate release by the astrocytes is regulated by a complex of proteins, the soluble N-ethyl maleimide-sensitive fusion protein attachment protein receptor (SNARE) complex (Montana V 2004), which includes synaptobrevin 2, Syntaxin 1 and synaptosome-associated protein of 23 kDa (SNAP-23) (Parpura V 1995, Crippa D 2006) along with a Ca^{2+} sensor Synaptotagmin 4. Cultured astrocytes have been shown to exhibit expression of synaptobrevin II, cellubrevin and syntaxin but not SNAP-25 (Parpura V 1995). Astrocytes have also been observed to

contain certain proteins which are important for sequestration of glutamate into vesicles. These proteins include: vacuolar type H⁺-ATPase (V-ATPase), which is responsible for creating the proton concentration gradient necessary for glutamate transport into vesicles (Araque A 2000, Bezzi P 2001) and the three known isoforms of vesicular glutamate transporters (VGLUT): 1, 2 and 3, which use the proton gradient created by V-ATPases to package glutamate into vesicles (Freneue RT Jr 2002, Anlauf E 2005). The glutamergic exocytosis of astrocytes has been noted to be potential targets for various pharmacological agents and molecular biological manipulations (Montana V 2004).

- **Production of oxygen free radicals and other reactive oxygen species:** These react with and damage a number of cellular and extracellular elements, of which vascular endothelium is particularly important. It may also act by means of redox signalling to initiate the apoptotic pathway.
- **Apoptosis:** In contrast to necrosis causing cell death in the ischemic core, apoptosis (programmed cell death) occurs in the peripheral neurons. Ischemic damage causes an early response in gene expression of Bcl-2 and p53, followed by release of proapoptotic molecules such as cytochrome c and apoptosis-inducing factor from mitochondria. This leads to the activation of caspases and other genes that augment cell death (Joza N 2001, Ekshyan O 2004). The caspase cascade can be activated either by an extrinsic or death receptor-dependent route; and an intrinsic or death receptor-independent (mitochondrial) pathway (Eldadah BA 2000). Ischemia also activates various other signalling pathways which ultimately culminate in cell death. Prominent among these, include p53 (Mihara M 2003), JNK (of MAPK family (Gupta S 1995)), c-jun (Hayashi T 2000), p38 (Barone FC 2000) and cyclin dependant kinase 5 (cdk-5) (Green SL 1997), which are potential targets for therapeutic intervention.
- **Neuroprotection:** Ischemic cascade also activated various neuroprotective mechanisms as a defense against apoptotic and necrotic cell death. These include:
 - *Bcl-2* gene family: Includes antiapoptotic and proapoptotic counter molecules. Antiapoptotic members suppress release of sequestered proteins; and can also modulate calcium fluxes and caspase activation in the ER and inhibit the active form of Bax in mitochondria (Thominius MJ 2003).
 - Heat shock protein 70 (HSP70): HSP 70 is one of the earliest to be released. Its mRNA is expressed within 1–2 h of ischemia, with subsequent deregulation in 1–2 days. In animal models, HSP70 inducer, geranylgeranylacetone, has shown efficacy in limiting infarct volume. It also acts by increasing *Bcl-2* expression and inhibiting monocyte/macrophage activation (Gifard RG 2004, Yasuda H 2005).
 - Prion protein (PrPc): PrP mRNA is upregulated during hypoxia, and it inhibits Bax-induced cell death in neurons. Studies have observed that PrPc deletion results in reduced post-ischemic Akt phosphorylation, enhanced caspase-3 activation, with resultant exacerbation of ischemic neuronal injury in animals (Weise J 2006).

- Neurotrophin-3 (NT-3): Neurotrophins are growth factors, especially essential for the survival and maintenance of neurons, where NT-3 expression may be important in defining neuronal survival after brain ischemia. Animal studies have suggested that altered NT-3 expression following ischemia may be part of a physiological neuroprotective response after excitotoxic or ischemic damage (Yang JT 1998). Interestingly, continuous low-dose treatment with NT-3 protected against striatal neuronal loss in mild neonatal hypoxic/ischemic brain injury (Galvin KA 2003), suggesting that it might possibly be of therapeutic benefit in ischemic brain injury in man.
- Granulocyte-colony stimulating factor (G-CSF): The initial studies by Schabitz et al. (Shabitz WR 2003) have unraveled the neuroprotective potential of the potent haematopoietic factor G-CSF in an acute stroke model. Further studies have demonstrated the role of G-CSF in activating multiple cell survival pathways, reduction of infarct volume after stroke and possible role in improving long term behavioral outcome and plasticity after cerebral ischemia in animal models (Schenieder A 2005), while it has also been noted to offer protection to human cerebral neurons following *in vitro* ischemia (Jung KH 2006).
- Interleukin-10: IL-10 gene expression is elevated in association with most major diseases in the CNS and aids survival of neurons and glial cells by blocking the effects of proinflammatory cytokines and promoting expression of cell survival signals (Strle K 2001). Studies have also been suggested that following a cerebral ischemic attack, IL-10 may have a neuroprotective role (Spera PA 1998). It has also been reported that there is a significant reduction in serum IL-10 levels of stroke patients soon after an acute event, indicating that the anti-inflammatory response is subsequently downregulated in this subset of patients (Perini F 2001).

Knowledge of these mechanisms is vital in order to salvage brain tissue undergoing ischemic damage. Neuroprotective drugs that scavenge reactive oxygen species, inhibit excitotoxic neurotransmitters or inhibit apoptosis, if used during the ongoing phase of ischemic injury may help act to achieve this goal. Deep barbiturate coma, and recently described, NXY-059, the disulfonyl derivative of the radical-scavenging spintrap phenylbutylnitron, is reported to be neuroprotective in stroke (Fernandez Gomez 2008).

Concept of Ischemic Penumbra

Cerebrovascular tissue undergoing ischemia has two layers: (a) outer layer of less severe ischemia (penumbra), supplied by collaterals, and contain cells which can be retrieved by timely therapeutic intervention; and (b) inner core of severe ischemia with blood flow below 10–25%, displaying necrosis of both neuronal as well as supporting glial elements. Following an ischemic injury, the center of the core is perfused at 10–12 ml/100 g/min or less, while the ischemic area around it (surrounded by the penumbra) is critically hypo-perfused at less than 18–20 ml/100 g/min and is at risk of dying within hours. In contrast, the penumbra is perfused at least likely at approximately 60 ml/100 g/min and is less likely to die (Heusman PU 2003). Neurons in the penumbra are mostly dysfunctional, but may recover if reperfused

in time. This forms the basis of current protocols which favor early pharmacological intervention for re-canalization of occluded vessel, since it will not only salvage neuronal and glial cells from the penumbra, but also glial cells from the central ischemic core zone, thereby markedly limiting the size of infarcted tissue (Turner R 2007). (See below figure 2 of Ischemic penumbra)

Figure 2. The Ischemic Penumbra: The ischemic penumbra represents compromised, but viable brain tissue lying distal to an occluded blood vessel. The top three MR images in this figure were taken in the same patient early after occlusion of the middle cerebral artery. The images are shown in the horizontal plane passing through the lateral ventricles. “Stunned, but not dead tissue” is detected by magnetic resonance imaging (MRI) techniques that assess (1) the spatial extent of the perfusion or blood flow deficit that presents as red and yellow areas on perfusion-weighted imaging (PWI, top middle image) and (2) severely damaged tissue in the ischemic core that presents as high-intensity areas on diffusion-weighted imaging (DWI, top left image) (Ebinger et al., 2009). In this patient, the perfusion deficit is larger than diffusion lesion. The top right image depicts the mismatch between core areas with a diffusion lesion (dark blue) and the larger areas with low perfusion (light blue-green). Over hours to days (see text), the core territory expands due to the complex cascades involving excitotoxicity, oxidative stress, programmed cell death mechanisms, and inflammation, as the initial trigger of energy failure ultimately progresses to infarcted tissue. The resulting infarct is shown in the image at the

bottom of the figure and is about the size of the initial perfusion deficit in this untreated patient. In later stages, some patients may also partially recover, in part due to endogenous mechanisms of repair and remodeling (Chopp et al., 2007). MRI scans courtesy of G. Alberts, Stanford.

CEREBRAL EDEMA AND ITS EFFECTS

This is of primary concern since it accounts for much of the death and disability. An understanding of the underlying mechanism, is important since management over the years have primarily addressed the effect without targeting the cause, which probably is attributable to the effects of neurogenic inflammation, mediated via neuropeptides, such as substance P. Klatzo classified edema as:

- Cytotoxic/cellular edema (Klatzo I 1987, Fishman RA 1992): Evolves within minutes to hours and are potentially reversible. It is characterized by swelling of all the cellular elements of the brain, including neurons, glia, and endothelial cells, due to failure of ATP-dependent ion (sodium and calcium) transport, as well as release of oxygen-derived free radicals.
- Vasogenic edema (Klatzo I 1987, Fishman RA 1992): Occurs over hours and days and are irreversible. It causes increased permeability of brain capillary endothelial cells to macromolecular serum proteins (e.g., albumin), resulting in an increase in extracellular fluid volume along with increased intracranial pressure (ICP).

This may displace the brain hemisphere; or shift one compartment of the brain, thereby compressing neurons, nerve tracts, and cerebral arteries. A sustained increase in pressure causes persistent ischemia; irreversible damage to brain cells; and, when severe may lead to cerebral herniation and potentially death. Initially acute hypoxia causes cytotoxic edema, which gives way to vasogenic edema with progression of infarction. This probably suggests that time is needed for the defects in endothelial cell function and permeability to develop.

EFFECTS OF ISCHEMIA ON STRUCTURAL INTEGRITY OF BRAIN

- Apart from the deleterious effect on brain cells, hypoxia also causes loss of structural integrity of brain tissue and blood vessels, partly through the release of proteases like matrix metalloproteases (MMP). Loss of vascular structural integrity results in the breakdown of the protective blood–brain barrier, manifesting as cerebral edema, along with secondary progression of brain injury (Adibhatla RM 2008). Studies have shown alterations of vascular endothelial receptor expression in ischemic stroke. Enhanced expression of vascular endothelial receptors is possibly mediated by both protein kinase C (PKC) and mitogen activating protein kinase (MAPK) which are the basis of treatment with PKC and MAPK inhibitors to limit the infarct volume (Edyinson L 2009).

- Brain ischemia also tends to activate the immune mechanism, which in some cases may be the cause for the exacerbation of damage and clinical deterioration of the patient. Experimental studies have shown that inhibition of the inflammatory process has led to the control of the extent of injury, an aspect which has gained paramount importance in understanding stroke and management of cases thereof (Ross R 1999, Ten Essecu R 2008, Adibhatla RM 2008).
- *Angiogenesis*: Extent of angiogenesis within the penumbra of ischemic stroke correlated with patient's survival time. This is mediated by either: (a) hypoxia inhibiting degradation of hypoxia-inducible factor-1 (HIF-1), which stimulates VEGF, which is essential for angiogenesis; (b) angiogenic growth factor secreted by inflammation-associated infiltrates [leukocytes, macrophages, damaged blood platelets] (Krupinski J 1994).

Hemorrhagic Stroke

This form of stroke occurs due to a blood vessel rupture in the brain. Its harmful effects are a resultant of: (a) hypoxia due to disrupted vascular supply; (b) irritant effect of releasing blood on brain parenchyma and vasculature; and (c) raised ICP due to continued bleeding, which may further restrict cerebral blood flow. In this respect, hemorrhagic strokes are more dangerous than ischemic strokes. There are two types of hemorrhagic stroke: intra-cerebral hemorrhage (generally occurs in small arteries or arterioles and is commonly due to hypertension, trauma, bleeding disorders, amyloid angiopathy, illicit drug use like amphetamines or cocaine, and vascular malformations), and sub-arachnoid hemorrhage (due to rupture of aneurysms from the base of the brain and bleeding from vascular malformations near the pial surface). It constitutes only 10–15% of all strokes (Escudero D 2008).

Atherosclerosis and Stroke

Atherogenesis is a decade-long process which involves luminal obstruction by cellular and extracellular substances. The pathogenetic process from onset of atherosclerotic changes in cerebrovascular or extracranial circulation to precipitation of acute ischemic stroke with its consequent cell damage is complex and many of the intermediary steps are not fully understood. Changes may manifest in the form of: (a) *fatty streak*, earliest lesions seen as yellowish areas of discoloration of intima, due to accumulation of lipid-filled macrophages (foam cells) in approximately 30% children below 5 years (Stary HC 1987); (b) *more advanced lesions with massive extracellular lipid* at the branching points of arterial vessels, in late childhood and early adolescence (Ip JH 1990); (c) *complicated fibrous plaques*: central acellular area of lipid covered by a cap of smooth muscle cells and collagen, seen in the third decade of life (IP JH 1990). Persons with risk factors for atherosclerotic disease (e.g., hypertension, hypercholesterolemia, cigarette smoking) tend to have clinically advanced atherosclerotic lesions with increased frequency. Sequence of events in atherogenesis is:

1. Injury to arterial wall: In his “response-to-injury” theory, Ross had hypothesized that, atherosclerosis is the effect of the complex interplay among monocytes, lipoproteins, platelets, lymphocytes, and smooth muscle cells in the intimal layer (Ross R 1999). Ip et al. In 1990 put forth a three-tier pathophysiologic classification system:

- *Type I injury:* Chronic minimal injury with functional alterations of endothelial cells without significant morphological changes, primarily caused by the turbulence of blood flow. Other contributory factors being hypertension, hypercholesterolemia, circulating vasoactive amines, immunocomplexes, viral infections, and tobacco smoke.
- *Type II injury:* Endothelial denuding and superficial internal injury, possibly due to toxic products released by accumulating macrophages in the intima. These changes may be accompanied by platelet deposition with or without thrombus formation, and subsequent thrombus incorporation.
- *Type III injury:* Manifested by deep intimal and medial damage, accompanied by marked platelet aggregation and mural thrombosis, generally following plaque rupture.

2. Role of monocytes and T-lymphocytes in foam cell transformation:

The next important events are:

- *Circulating monocyte adhesion:* Abnormal shear stress at atherosclerotic lesion-prone sites in the circulatory system enhances the production of certain transcription factors, which promotes the expression of endothelial vascular cell adhesion molecule (VCAM), which is imperative for monocyte binding to endothelial cells (Gimbrone MA Jr 1995).
- *Monocytes insinuation* between the tight junctions of the endothelial cells to enter the subendothelial space.
- *Activation of immune mechanism:* In the form of T-lymphocyte activation, in both early fatty lesions and in advanced fibrous lesions, which helps monocytes migration and its transformation into “foam cell”.

3. Oxidation of LDL-cholesterol: Oxidation of LDLcholesterol induced by free radicals produced by macrophages, endothelial cells, or smooth muscle cells, participates by:

- a) Formation of foam cells;
- b) Cytotoxic properties promoting endothelial injury;
- c) Chemoattractant for circulating monocytes; and
- d) Inhibiting egress of macrophages from plaques (Adibhatla RM 2008).

4. Smooth muscle cell migration and proliferation: A number of molecular factors may play a role in this vital plaque-forming process. They include growth factors (e.g.,platelet-derived growth factor, or PDGF, a polypeptide released from blood platelets and endothelial cells that may attract smooth muscle cells to the intima and encourage them to divide); eicosanoids (which can stimulate the hydrolysis of

cholesterol ester, producing free cholesterol); certain cytokines (e.g., tumor necrosis factor, interleukin-1 and interferon); and nitric oxide which acts to dilate blood vessels.

5. **Role of platelet:** Platelet aggregation and adhesion promoted by toxic products released by macrophages and by moderate damage to the internal surface with denudation of the epithelium have vital roles in the progression of atherosclerosis (Ip JH 1990).
6. **Plaque fissuring and thrombus formation:** The process of plaque destabilization (fissuring and rupture, followed by thrombus formation) is not fully understood.
 - **Plaque fissuring is possibly due to:**
 - a) Loss of an internal lattice of collagen supporting the cap of the plaque., making it vulnerable to circumferential stress during systole;
 - b) Infiltration of the cap tissue with foam cells, which possibly weakens the tissue by passively distorting the spatial arrangement of the connective tissue matrix or by actively destroying connective tissue matrix protein by lyric mechanisms (Slager CJ 2005).
 - **Thrombus formation occurs by:**
 - **Platelet activation:** On coming in contact with the sub-endothelial collagen, exposed by way of plaque rupture, circulating platelets get activated, and subsequently aggregate and adhere, through interaction with platelet surface receptors (most important being GP-Ib-IX) and sub-endothelial protein ligand von Willebrand factor (VWF). An association between elevated vWF concentrations and arterial thrombosis has been described (Jansson JH 1991).
 - **Platelet activation and blood flow:** Under high fluid shear-stress conditions, as in atherosclerosis, there is evidence that platelet aggregation depends on the binding of VWF to platelet GPIIb/IIIa, blockade, of which inhibits platelet aggregation and thrombus formation without disturbing the initial platelet adhesion (Stoll G 2008).
 - **Activation of the coagulation cascade:** Endothelial injury constitutes the primary impetus for the initiation of the extrinsic pathway of the coagulation cascade. Activated platelets, apart from forming the backdrop of the clotting process, also acquire enhanced capacity to catalyze interactions between activated coagulation factors (which normally circulate as inactive precursors: *zymogens*). Factor Xa, is the active catalytic component of the “prothrombinase” complex, which converts prothrombin to thrombin. Thrombin cleaves fibrinopeptides (FPA, FPB) from fibrinogen, allowing the resultant fibrin monomers to polymerize, and converts Factor XIII to XIIIa, which crosslinks (XL) the fibrin clot. Thrombin accelerates the process by its potential to activate Factors V and VIII, while a number of natural plasma inhibitors retard clotting, including C1-inhibitor (C1 INH), tissue factor pathway inhibitor (TFPI), and antithrombin II (ATIII). The fibrin molecules aggregate together, trapping platelets, erythrocytes, and leukocytes to form the thrombus. Subsequently, there is a tendency for the clot to enlarge as blood flow slows around it, resulting in enlargement of size (“*propagating thrombus*”).

- **Physiologic-subtypes of thrombosis related ischemic stroke:**

Ischemic stroke with different etiologies, possibly have a link based on the process of thrombosis:

- Atherothrombotic occlusion of larger arteries (e.g., carotid, middle cerebral, basilar): Most common causes of primary large vessel occlusive cerebrovascular disease, and also is the most common cause of stroke.
- Embolism is the second most common cause of stroke. Most are due to cerebral arterial atherothrombosis; or may also arise from other cardiogenic sources and deep vein thrombosis.
- Microatheroma of an influx of fat-like materials (lipohyalinosis) affects small vessels; and most prominently causing lacunar strokes.

7. *The potential outcomes of plaque fissuring:* It includes:

- a. Sealing of the fissure with fibrosis of incorporating thrombus; or
- b. Mural intra-intimal and intra-luminal thrombosis, resulting in partial or transient reduction in blood flow (precipitating transient ischemic attacks: TIA). It may progress to occlusive thrombosis, which, if persistent due to absence of collateral flow, can lead to ischemic stroke (IP JH 1990).

8. *Evolution of cerebral atherothrombosis:* Thrombosis may evolve over a few minutes, or take hours or even days. A stroke that is actively progressing as a direct result of increasing occlusion and ischemia is termed '*stroke in evolution*' or '*progressing stroke*'. A large blood vessel may evolve over a longer period of time, as compared to a smaller vessel, and there may be warning signs like TIA. Damage in ischemic stroke may result not only from infection, but also from edema, which generally peaks in 2–5 days. (I) *Hemorrhagic conversion*: Natural consequence of reperfusion of blood through damaged blood–brain barrier, in ischemic stroke, generally has 'bland' infarction associated with secondary bleeding. This is referred to as hemorrhagic conversion or hemorrhagic transformation (HT), and is characterized by gross parenchymal hematoma with possible intraventricular extension, midline shift and herniation; along with widespread leukocyte infiltration and macrophage invasion (Teal PA 1992). HT may be seen as hemorrhagic infarction (HI) or, less commonly, parenchymatous infarction (PH). Though both have different incidences, pathogenesis, and clinical outcome, but distinguishing HI and PH on CT may be difficult. On CT, HI appears as a discontinuous heterogeneous mixture of high and low densities occurring within the vascular territory of the infarct. In contrast, PH appears as a discrete, homogeneous collection of blood that often exerts mass effect and may extend beyond the original infarct boundaries or even into the ventricles (Teal PA 1992).

Recent studies have suggested the role of an abnormal expression of some matrix metalloproteinases (MMPs) which can degrade almost all components of the extracellular matrix and basal lamina such as laminins, fibronectin, or type IV collagen, weakening brain microvessels and predisposing them to rupture and increasing the risk of cerebral hemorrhage and precipitate hemorrhagic transformation events after stroke (Gasche Y 1992). Previous animal models (Heo JH 1999, Rosenberg GA 1996) have demonstrated an abnormal

expression of MMP-2 (Galatians A) or MMP-9 (Galatians B) after cerebral ischemia and in lipopolysaccharide-injured brains (Mun-Bryce S 1998), contributing to brain injury and BBB breakdown. Further, Asahi et al. 2001 and Sumii et al. 2002 reported that pharmacological or genetic inhibition of MMP-9 has caused a significant reduction in size of the infarct, as well as the risk of hemorrhagic complications, while Wang et al. 2003 and Tsuji et al. 2005 noted tissue plasminogen activator-associated hemorrhage and edema appeared to be correlated to MMP-9 dysregulation. Investigations dealing with ischemic stroke in human subset have revealed high MMP-9 levels in peripheral blood, with MMP-9 levels showing correlation with poor neurological outcome, infarct growth, and hemorrhagic transformation events (Montaner A 2001, 2003). Rossel et al. 2008 have reported a strong neutrophil infiltration in the infarcted and hemorrhagic areas with local high MMP-9 content closely related to basal lamina collagen IV degradation and blood–brain barrier breakdown. Hemorrhagic infarction (HI) occurs regularly in the natural evolution of acute embolic stroke and is usually asymptomatic. Autopsy studies of HI may vary from patchy petechial bleeding to more confluent hemorrhages, with an occurrence rate ranging from 51% to 71% of recent embolic strokes (Teal PA 1992). According to another estimate (Leonard AD 1992), approximately 20% of patients with cardioembolic stroke have hemorrhagic transformation in the infarcted zone, usually occurring within 48 h, and is rare in the first 6 h. HI has been often explained as a result of reperfusion of the vascular bed of the infarct, such as would occur after fragmentation and distal migration of an embolus or after early reopening of a large vessel occlusion in the setting of a large infarction; the full pressure of arterial blood into hypoxic capillaries results in a diapedesis or red cells through their hypoxic walls (Mohr JP 1992). It has been observed that HI may develop in areas distal to a persisting occlusion, suggesting that reperfusion is not always a prerequisite for this phenomenon. Many studies have found strong correlation with risk factors like:

- 1) One or more surges of arterial hypertension;
- 2) Associated hyperglycemia; and
- 3) Restoration of blood flow to ischemic territories.

Possible mechanism for this is marked tissue energy depletion accompanied by acidosis damaging brain vessels, causing leakage of edema fluid and red blood cells.

Parenchymatous infarctions (PH) occur less frequently, but are often symptomatic due to extension and mass effect beyond the original infarct territory (Teal PA 1992). In contrast to HI, it has been proposed that the pathogenesis of PH may involve “ischemic necrosis resulting in the rupture of small penetrating vessels analogous to hypertensive hemorrhage, leading to massive bleeding”. Trials of thrombolytic therapy for acute ischemic stroke, has revived interest in this, since PH appears to be associated with anticoagulation therapy (Adhi bhatla RM 2008, Pandian JD 2009).

Free Radicals in Cerebral Damage

A vast amount of data implicates oxygen-derived free radicals (especially superoxide and hydroxyl radicals) and high-energy oxidants (such as peroxynitrite) as mediators of inflammation in ischemia/reperfusion injury (Cuzzocrea S 2001). Free radicals are highly

reactive molecules generated predominantly during cellular respiration and normal metabolism. Imbalance between cellular production of free radicals and the ability of cells to defend against them is referred to as oxidative stress (Valko M 2007). After brain injury from ischemic stroke, the production of ROS dramatically increases, leading to tissue damage via several different cellular, molecular pathways, and mechanical pressure (Figure 3).

ROS can cause damage to cellular components such as lipids, protein, and nucleic acids, leading to subsequent cell death (Janardhan V 2004). Damage can become more widespread due to weakened cellular antioxidant defense systems in ischemia. ROS are the major stimulators of inflammatory cytokine production (such as interleukin-1, tumor necrosis factor- α , and interferon- γ) and protease secretion by microglia, leukocytes, and resident cells of the neurovascular unit (Haddad JJ 2002). As these neuroinflammatory mechanisms become activated, alterations in cytokine profiles, adhesion-molecule expression, and tight-junction components mediate further vascular leakage. Significant evidence exists suggesting that ROS are involved in every fundamental physiological step that leads to neuronal death (Cao W 1988) and thus are considered an important target in developing an effective stroke therapy (Juurlink BH 1997).

Figure 3. Schematic showing different types of stroke and cascade of events following ischemia.

Oxidative and Nitrosative Stress Oxidative and nitrosative stress are also powerful mediators of ischemic injury. In one scenario, the redox environment of cells modulates signal transduction cascades that tip the balance between prodeath and prosurvival pathways (Crack and Taylor, 2005). In the second scenario, ROS and perhaps reactive nitrogen species, including peroxynitrite, act directly as executioners of cell death (Chan, 2001). The brain appears particularly vulnerable to radical-mediated attack because of its limited antioxidant defenses (Adibhatla and Hatcher, 2010). Until recently, it was accepted that during ischemia ROS were generated principally by mitochondria, a well-known ROS source during electron transport and oxidative phosphorylation. However, it was recently shown that NADPH

oxidase generates the majority of superoxide anion produced *in vivo* and *in vitro* during NMDA receptor activation and ischemia (Brennan, 2009; Girouard, 2009). Thus, the mitochondrion does not appear to be the major source of radicals following NMDA receptor activation. However, the close proximity of NADPH oxidase to neuronal mitochondria (Girouard, 2009) raises the possibility that this enzyme generates “kindling” ROS that promote mitochondrial uncoupling, triggering a secondary ROS surge from mitochondria (Figure 3). These observations point to NADPH oxidase as a potentially important therapeutic target in stroke but also highlight the need for a better understanding of the interaction among the different ROS sources and the relative contribution of vascular versus neuronal sources. In this regard, a surprising finding has been that activation of NMDA receptors increases ROS both in neurons and vascular cells (Girouard, 2006), suggesting a role of vascular ROS in excitotoxic brain damage. Although this observation emphasizes the close relationships between vessels and neurons (see Protecting the Neurovascular Unit), it has not been established how vascular oxidative stress may contribute to tissue outcome in excitotoxic brain injury.

NO and related oxidation products are key players in excitotoxicity. Reactive nitrogen species have important cellular effects, such as inhibition of key mitochondrial enzymes, facilitating mitochondrial transition pore formation, DNA damage, PARP activation, and activation of Ca^{2+} -permeable TRPM7 channels (Aarts and Tymianski, 2005; Pacher, 2007). As a potential second mechanism, NO modifies protein groups by covalently attaching two cysteine residues forming an S-nitrosothiol derivatives. This posttranslational modification significantly impacts cell survival by altering, for example, the function of critical regulatory proteins such as campuses, metalloproteases (GU et al, 2002), and the glycolytic enzyme GAPDH (Nakamura and Lipton, 2009). As NO has the potential to target a number of specific cysteine residues to alter protein function, the impact of S-nitrosylation is (largely) underexplored in the ischemic process. Taken together, the experimental evidence implicating oxidative and nitrosative stress in stroke is strong. But the translation of these fundamental concepts into clinical applications has proven to be challenging. Most recently, a nitron-based radical spin trap failed in the final phase 3 clinical trial for acute ischemic stroke (Shuaib, 2007). And more broadly, the history of antioxidant therapies in clinical trials for neurodegeneration has been littered with many disappointments (Kamat, 2008). Overproduction of reactive nitrogen and oxygen species are surely damaging to brain cells. But at lower, homeostatic levels, radicals are critical signaling molecules participating in normal neuronal and vascular function (Faraci, 2006). Finding novel ways to scavenge or suppress deleterious radicals without interfering with endogenous signaling will be important to design effective therapies. As discussed above for excitotoxicity, a desirable strategy would be to develop drugs that only become activated by the pathological state intended for inhibition, i.e., during oxidative stress (Lipton, 2007b). Another approach would be to test antioxidant molecules with pleiotropic properties, such as activated protein-C (APC). APC blocks ROS generation, suppresses postischemic inflammation, and blocks apoptosis in neurons and endothelial, thereby providing both parenchymal and vascular protection (Yamaji, 2005; Cheng, 2006; Liu, 2004). APC as well as other pleiotropic agents with a broad spectrum of activity in experimental stroke are undergoing clinical trial testing (Ginsberg, 2009).

Excitotoxicity

Cerebral ischemia initiates a cascade of detrimental events including glutamate associated excitotoxicity, membrane lipid degradation, DNA damage, formation of reactive oxygen species and acute inflammation, which lead to the disruption of cellular homeostasis and structural damage of ischemic brain tissue. Excitotoxicity and calcium overload are major factors contributing to the early stages of ischemic cell death. The canonical pathway asserts that glutamate, the most abundant neurotransmitter, accumulates into the extracellular space as a consequence of energy and ion pump failure, as well as the failure of re-uptake mechanisms (Choi and Rothman, 1990). The glutamate overload leads to prolonged stimulation of AMPA and NMDA ionotropic receptor subtypes to dramatically enhance the influx of calcium, sodium, and water into neurons. Massive calcium influx activates catabolic processes mediated by proteases, lipases, and nucleases (Ankarcrona, 1995). In addition, activation of nNOS, PLA2, and other Ca^{2+} -dependent enzymes leads to production of NO, arachidonic acid metabolites, and superoxide, which act as additional triggers of cell death (Dirnagl, 1999; Lo et al, 2003). For these and other reasons, oxidative phosphorylation becomes uncoupled; leading to further ATP depletion, ROS production, and release of stored Ca^{2+} from mitochondria, further accelerating a series of catastrophic events that lead to acute cell death. Despite the validation of glutamate toxicity in the laboratory setting and its enormously positive impact on the quest for new therapeutics in neuroscience, numerous clinical trials targeting NMDA and AMPA receptors have failed to improve outcome in stroke patients (Ginsberg, 2009). Although replete with shortcomings in trial design and implementation, the failure to translate has reinforced the notion that the glutamate hypothesis may have oversimplified the complexity of the cell death process and underestimated the diversity of expressing cell types as well as the heterogeneity of glutamate responses following receptor overstimulation in stroke. Moreover, it is likely that NMDA-AMPA pathways comprise only a subset of routines disrupting ionic imbalance following glutamate receptor activation. As originally conceived, the NMDA-AMPA model did not consider the delayed and invariably fatal glutamate-independent calcium influx following oxygen-glucose deprivation or the failure of the glutamate receptor blockade to halt cell death after very intense oxygen-glucose deprivation (Aarts, 2003).

Equally importantly, it could not account in an obvious way for the death of non-neuronal cell types such as astrocytes, vascular cells, or microglia in ischemic tissue. An alternative viewpoint is that the drugs tested in clinical trials were poorly chosen, because many of them block all receptor functions (Lipton, 2007a). As a result, the dosing may have been suboptimal, due to the development of untoward side effects that prevented dose escalation to neuroprotective levels. A more suitable approach would be to use therapeutic agents that selectively target excessive channel opening (e.g., uncompetitive inhibitors with a relatively fast offrate, such as mountain (Orgogozo, 2002; Mobius and Stoffler, 2002; Lipton, 2006; Kavirajan and Schneider, 2007), thereby retaining normal receptor functions (Lipton, 2007a).

To add to the complexity, it is now known that NMDA receptor location and subunit composition differently regulate neuronal survival or death, although the strength of the calcium signal may specify the fate of neurons best following NMDA over-activation (Stanika, 2009). With notable exceptions, selective enhancement of synaptic receptors (in which NR2A peptide subunits predominate over NR2B) promotes neuronal survival, whereas activating extra synaptic receptors (in which NR2B peptide subunits predominate over

NR2A) promote cell death (Chen, 2007), in part, by activating death-associated protein kinase 1 (Tu, 2010). Turning CREB-dependent signaling and BDNF expression up or down is critical for cell fate determination during NMDA receptor activation. The MAP kinase family members P38 and ERK1/2 participate, most likely by phosphorylation-dependent regulation of sub-membrane scaffolding proteins and NR2A and NR2B receptor subunits (Hardingham, 2002). Under ischemic conditions, the vulnerability to cell death is reduced when postsynaptic scaffolding proteins are modified, and PSD-95 binding is prevented (Cui, 2007). Moreover, successfully targeting the glutamate receptor complex early on would also diminish the opening of the downstream channels, e.g., transient receptor potential channels (TRP) and acid-sensing ion channels, as well as suppress the frequency of cortical spreading depolarizations (see below), ongoing within the ischemic penumbra. Hence, understanding and leveraging the repertoire of diverse responses and mediators at the receptor and second messenger level can only enhance possibilities for successfully targeting excitotoxicity for the treatment of ischemic injury.

Calcium Dysregulation: It is also known that increased calcium influx from glutamate receptor overactivation combined with release of Ca^{2+} from mitochondria and other stores (e.g., endoplasmic reticulum) may not fully account for the irreversible buildup of intracellular Ca^{2+} after excitotoxic stimulation. Other channels and ion pumps activated during ischemia in addition to glutamate receptors have been implicated in the Ca^{2+} accumulation. These include the $\text{Na}^{+}/\text{Ca}^{2+}$ exchange (Bano, 2007) hemichannels (Contreras, 2004), acid-sensing ion channels (Xiong et al., 2004), volume-regulated anion channels (Kimelberg et al., 2006; Simard, 2007), and TRP channels (Aarts and Tymianski, 2005). In particular, ASIC1a, activated by ischemia-induced acidosis, is involved in the Ca^{2+} influx and its inhibition is neuroprotective (Simon, 2006). ASICs are stimulated within the pH range commonly found in ischemic brain tissue, thus explaining the well-established link between acidosis and worsening of ischemic outcome in animals and humans. Failure of Ca^{2+} efflux mechanisms, especially the $\text{Na}^{+}/\text{Ca}^{2+}$ exchanger also contributes to the Ca^{2+} accumulation. Prostaglandin E2 EP1 receptors have a role in the failure of the $\text{Na}^{+}/\text{Ca}^{2+}$ exchanger during ischemia, and their inhibition is markedly neuroprotective (Abe, 2009; Kawano, 2006). Therefore, targeting Ca^{2+} influx-efflux mechanisms may be a valuable approach to counteract Ca^{2+} dysregulation and associated injury in conjunction with novel drugs targeting glutamate receptors.

Cortical Spreading Depolarizations

In addition to excitotoxic events at the molecular and cellular level, massive release of glutamate and ionic imbalance negatively impact the evolution of ischemic injury at the tissue level. Cortical spreading depolarization (CSD), a high energy consuming phenomenon akin to the cortical spreading depression of Leao, is triggered by high levels of extracellular glutamate and K^{+} and is characterized by slowly propagating massive depolarization of neurons and astrocytes along with drastic disruption of ionic gradients (Somjen, 2001). Electrophysiological and imaging data convincingly demonstrate CSD in patients with ischemic stroke (Dohmen, 2008). In experimental animals, a single cortical spreading depolarization expands the area of severe hypoperfusion by more than 20% (Shin, 2006). In fact, it appears that a greater frequency, but more importantly, duration of DC shifts

correspond to accelerated infarct maturation and core expansion (Mies, 1993; Back, 1996). The infarct expansion is probably due to mismatch between high metabolic demand to support membrane re-polarization and marginal tissue perfusion due to constrained penumbral blood flow (Back, 1996). Hence, suppressing CSD may prove worthwhile for reducing infarct maturation. Notably, the noncompetitive NMDA receptor antagonist ketamine markedly suppressed CSD frequency in head injury patients (Sakowitz, 2009), but it is unclear whether it improved clinical outcome. By contrast, irreversible depolarizations resistant to NMDA receptor antagonists (anoxic depolarization) developments in the ischemic core territory (Nellgiad and Wieloch, 1992) and are probably terminal events contributing to severe ionic imbalance and tissue failure.

INFLAMMATION

Focal ischemia evokes a robust inflammatory response that begins within a few hours of onset and typifies the secondary or delayed response to ischemia. It involves the activation of microglia and astrocytes as well as an influx of hematogenous cells recruited by cytokines, adhesion molecules, and chemokines across the activated blood vessel wall. Stimulated brain cells and blood vessels then communicate with one another through a complex network of paracrine and autocrine signaling. The highly choreographed response evolves over many days, with multiple signals and targets triggering expression of novel proteins and secondary infarct expansion (Kleinig and Vink, 2009). Innate and adaptive immune systems participate as well. At least early on, inflammation amplifies the ischemic lesion, but, as discussed later, it may set the stage for tissue repair in the late post-ischemic period. A number of therapeutic trials designed to target the inflammatory response have failed to show clinical benefit (Sughrue, 2004), underscoring the need to clarify further the complexities of acute and delayed postischemic inflammatory signaling within the brain. As noted above, cerebral blood vessels are the first to be exposed to the ischemic insult, and their reaction to injury sets the stage for the inflammatory response. Early on, production of cytokines, such as TNF- α and IL1b, in vascular cells and perivascular microglia-macrophages upregulates adhesion molecule expression (e.g., ICAM-1, P and E-selectin) and, along with integrins, promote leukocyte rolling and sticking to the vessel surfaces (Zhang 1998). Neutrophils are the first blood-borne cells to be recruited into the brain, followed by monocytes and, starting on days 1–2, lymphocytes. As the brain's primary immune cell, activated microglia transform into macrophages and accumulate at the border zone along with blood-borne macrophages to clear debris and dead cells and produce pro-inflammatory mediators and toxic molecules (Schilling, 2003). Molecules released from injured or dying brain cells also contribute to the inflammatory response. In particular, products from cells undergoing oxidative stress and necrosis, for example lipopeptides, advanced glycation end-products (AGE), modified lipids, heat shock proteins, hyaluronic acid, and the nuclear protein HMGB1, lead to activation of the innate immune system by engaging toll-like receptors (TLRs). TLRs are expressed in multiple cells and, in conjunction with CD36, receptors for AGE (RAGE), and other scavenger receptors, may serve to detect “danger signals” triggering NF κ b-dependent inflammatory signaling (Oppenheim and Yang, 2005; Wang, 2007). PARP activity appears to function as an NF κ b coactivator (Chiarugi and Moskowitz, 2003), with therapeutic potential

for delayed administration of PARP-1 inhibitors (Kauppinen, 2009). Besides NF- κ B, other transcriptional activators, including activator protein-1, STAT-3, interferon regulatory factor 1, and C/EBP beta, exert a proinflammatory effect (Kapadia, 2006; Iadecola, 1999), while PPAR γ acts as a negative modulator of postischemic inflammation (Kapadia, 2008). In addition to neutrophils and monocytes, T cell subsets have recently been implicated as modulators of secondary infarct progression. Treg cells express the antiinflammatory cytokines IL10 and TGF- β and normally dampen the immune response by suppressing T cell effector activity (Liesz, 2009). Secondary infarct progression is impacted by a second subset of invading T lymphocytes, gamma-delta T cells, a source of the proinflammatory cytokine IL-17. After deletion of IL-17, infarct size decreases (Shichita, 2009).

These findings support the notion that taming post-ischemic inflammation may block secondary events that extend brain injury. However, as noted below, during the later stages in the injury process, inflammation promotes critical events necessary for tissue repair. Therefore, therapeutic interventions targeting post-ischemic inflammation should be mindful of temporal considerations by minimizing the destructive potential of inflammation in the acute phase while enhancing its beneficial contributions to tissue repair in the late stages of cerebral ischemia. Necrosis, Necroptosis, and Autophagy: The Execution Necrosis and apoptosis are the principal mechanisms of cell death after ischemic injury, and the details of both have been mentioned (Yuan, 2006, 2009). Depending in part upon the magnitude, type of stimulus, and cell type, a number of cell death triggers promote necrosis or apoptosis, although cellular features of apoptosis and necrosis are sometimes found together in dying ischemic cells. Probably due to its ATP dependence, apoptotic cell death is prominent after milder injury and is more delayed (Bonfoco, 1995), although severe ischemia is associated with early-onset of caspase cleavage, enzyme activation, and acute cleavage of substrate proteins (Namura et al., 1998). Apoptosis and necrosis can be induced by multiple triggers, such as Ca²⁺ overload or oxidative stress. Mitochondria play an essential role in both (Schinzel, 2005), serving as a reservoir for proapoptotic and antiapoptotic proteins and cytochrome C. One such protein apoptosis-inducing factor (AIF) is released from the outer membrane of mitochondria in response to activation of the nuclear protein PARP and generation of a PAR polymer, its toxic product (Yu, 2006). AIF then translocates to the nucleus to promote a caspase-independent form of cell death, in part by promoting DNA fragmentation and chromatin condensation. Release of mitochondrial proteins sets in motion (or suppresses) multiple caspase-dependent and -independent processes to dismantle critical homeostatic and repair mechanisms. Despite the expression of executioner procaspases, activated caspases, and caspase cleavage products, classic apoptotic morphology is rarely found in humans within the adult ischemic brain. However, it does appear more prominently in the ischemic brains of neonates (Ferriero, 2004). Until now, necrotic cell death was defined as unregulated, unprogrammed, and lacking cell signaling events. It is the predominant form of ischemic cell death. It was recently shown that certain cells, including those within the brain, possess a molecular switch that determines whether cells die by necrosis or apoptosis in a TNF-dependent way (Holler, 2000). In this cell death variation, necrosis are triggered by two kinases, RIP 1 and RIP 3, reciprocally interacting, often in the presence of an apoptosis inhibitor (Cho, 2009). Activated RIP3 is capable of stimulating enzymes such as the glycogen-degrading enzyme, glycogen phosphorylase, to steer TNF-induced apoptosis toward necrosis, in part through bursting energy metabolism and ROS generation (Zhang, 2009). Nec-1, a small-molecule inhibitor of RIP-1, decreases ischemic cell injury in models of

ischemia-reperfusion and improves neurological outcome, suggesting RIP-1 as a potential therapeutic target (Degterev, 2005). Autophagy, an energy-dependent process implicated as a cell death mechanism, is used by eukaryotes to degrade and recycle subcellular organelles. Its precise role in the death process is controversial because autophagic activity may be cytoprotective, at least in some disease models, e.g., polyglutamine expansions or in aging models (Levine and Kroemer, 2009). In other disease models, such as in neonatal hypoxia-ischemia, autophagy reportedly promotes cell death (Puyal, 2009). Precisely how this is accomplished remains for further study.

Inflammation and Stroke

Currently there is increasing evidence that some form of inflammatory mechanism plays a role in the development and progression of stroke, especially in the setting of cerebral ischemia due to subarachnoid hemorrhage, head injury or cardiac arrest. It has been reported that low grade inflammation with raised levels of C-reactive protein (CRP) is an independent risk factor for stroke and TIA (Di Napoli M 2001). In pediatric population, inflammation without significant atherosclerosis has been associated with stroke. Novel imaging techniques have been adopted to facilitate *in vivo* observation of the dynamic effects of inflammation in causing brain tissue damage and neurologic outcome.

Inflammatory conditions associated with stroke. Stroke has been associated with a wide range of systemic inflammatory conditions. It may be associated with primary vasculitis, like giant cell arteritis, primary angitis of CNS, Takayasu's arteritis; vasculitis secondary to SLE, progressive systemic sclerosis, rheumatoid arthritis; and other inflammatory conditions like inflammatory bowel disease (IBD) and sarcoidosis. Fortunately the majority of these are rare, with stroke being an unusual complication in most cases (Emsley HC 2002, Hu Z 2000).

Infective Conditions Associated with Stroke

A number of acute and chronic infective conditions have been observed to precede a stroke. Most often these are of respiratory and bacterial origin, occurring within the previous month. These cases tend to present with more neurological deficit as compared to ones without infection (Campbell LA 2000, Grayston JT 1990, Tarnacka B 2002). Of the chronic infections *Chlamydia pneumoniae* has been known to affect macrophages/monocytes, endothelial cells, and vascular endothelium and thus having a pivotal role in atherogenesis. Evidence to this regards have been in the form of demonstration of the organism in atherosclerotic plaques of coronary artery and middle cerebral artery (Campbell LA 2000), and seropositivity in more than 50% individuals in their sixth decade (Grayston JT 1990). Currently, an acute recrudescence of infection (diagnosed by immunoglobulin M titers) is associated with acute stroke and TIAs. Similarly, increased serum levels of immune complexes containing chlamydial lipopolysaccharide have also been associated with increased stroke incidence and worse clinical outcome (Tarnacka B 2002). *Helicobacter pylori* have also been implicated in stroke pathogenesis, with one report emphasizing association with small vessel occlusion. However, seropositivity for *H. pylori* may be an independent risk factor for ischemic stroke (Emsley HC 2002, Grau AG 2001). Recurrent or

chronic respiratory infection (independent from acute episodes), herpes virus, periodontal infection (gingivitis or periodontitis) has been suggested to be independent risk factors in ischemic stroke (Emsley HC 2002, del Zepo G 2000). Neurological complications, though, are common in human immunodeficiency virus infections, associated with stroke remains unclear. It has been suggested to conduct randomized intervention studies, especially in cases of *C. pneumoniae*, in order to resolve the uncertainty over the temporal sequence of infection and stroke.

Inflammatory Mediators in Acute Stroke

The onset of ischemic cascade heralds the initiation of various processes, including inflammation, excitotoxicity, nitric oxide production, free radical damage, and apoptosis, all of which play a role in tissue injury. The molecular consequences of brain ischemia include temporal changes in cell signaling, signal transduction, metabolism, and gene regulation/expression. Currently these are potential therapeutic targets to minimize tissue loss and neurologic deficit by lessening the proportion of penumbral tissue recruited into the infarcted core. Inflammation occurs both by the molecular and cellular components at the blood-microvascular endothelial cell interface (Tan asesco 2008, Adibhatla 2008). With the onset of brain ischemia, microglia, astrocytes, endothelial cells, and neurons are known to release a number of cytokines, like interleukin-1 β (IL-1 β) and tumor necrosis factor- α (TNF- α), which enables leukocyte recruitment, activation, and the final adhesion to the endothelium of the cerebral microvasculature. These activated leukocytes obstruct the vascular channel, followed by transmigration in the infected areas along with monocytes/macrophages. Similarly, reperfusion, and systemic inflammatory processes, both before and after acute stroke, may also stimulate the inflammatory response, thus hampering the efficacy of thrombolytic therapy.

Inflammatory Gene Expression

Cerebral ischemia is known to upregulate the expression of a number of proinflammatory genes like transcription factors, heat shock proteins, cytokines, chemokines, and adhesion molecules. Among this transcription factor, nuclear factor (NF)- κ B, has been demonstrated to regulate expression of TNF- α , IL-1 β , IL-6, nitric oxide synthase (NOS), cyclooxygenase-2 (COX-2) and intercellular adhesion molecule-1 (ICAM-1) during *in vitro* conditions (Tan asesco 2008, Adibhatla 2008, del Zoppo G 2000). In the periphery (NF) - κ B, was expressed by activating macrophages, monocytes, lymphocytes, endothelial cells, fibroblasts, platelets, while in cerebral infarctions (NF)- κ B has been seen to be induced in activated microglia and glial cells (Terai K 1996).

Cytokines

These are polypeptides associated with inflammation, immune activation, and cell differentiation or death. In systemic setting these are produced by activating macrophages, monocytes, lymphocytes, endothelial cells, fibroblasts, platelets, and many other cell types,

whereas in CNS their source are activated microglia. Proinflammatory cytokines like TNF α , IL-1 β lead to parenchymal damage, while IL-10 and IL-1 receptor antagonist (IL-1ra) have an anti-inflammatory and neuroprotective role.

- *Tumor necrosis factor- α* : Permanent or focal MCAO has been associated with induction of TNF- α mRNA. The effects of this proinflammatory cytokine have been controlled by administration of soluble TNF-receptor 1 (sTNF-R1) or anti-TNF- α monoclonal antibody. The TNF - α expression appears sequentially in ischemic core, periinfarct areas, adjacent brain, followed by remote areas. CSF and blood levels have been elevated in most ischemic stroke patients, within first 6–12 and 24 h of onset. In lacunar infarcts, elevated levels have been associated with early neurologic deterioration and poor functional outcome. Elevated sTNF-RI and sTNF-RII concentrations are associated with carotid atherosclerosis, while sTNF-RI concentrations are increased in patients with acute ischemic stroke and infection (Adibhatla RM 2008, Emsley HC 2002, Buttini M 1996, Elkind MS 2002).
- *Interleukin-1*: Experimental studies have proved its proinflammatory property, which have been neutralized by IL-1ra administration (Emsley HC 2005). In contrast, neutralizing antibody to IL-1ra has resulted in enhancing the effects of brain ischemia. Increased IL-1 messenger RNA (mRNA) expression in peripheral mononuclear cells have been seen 1–3 days after onset of symptoms and reducing to normal levels by 20–31 days (Kostulas N 1999). Elevated plasma IL-1ra levels have been seen in patients with acute ischemic stroke within 4 $\pm$ 2 days (Beamer NB 1995, Emsley HC 2002, Adibhatla RM 2008).
- *Interleukin-6*: Cerebral ischemia is a potential bioactivator of IL-6 mRNA, especially in middle cerebral artery occlusion (MCAO) in animal models. Intracerebro-ventricular injection of anti-inflammatory IL-6 has been associated with significant reduction in ischemic damage. In a clinical study, circulating IL-6 levels were found to increase significantly, reaching a plateau between 10 h and 3 days, before returning to baseline by 7 days. It also correlated with volume of computed tomography of brain lesion, as well as, poor functional and neurologic outcome. Similar correlation in CSF studies has also been noted. However, IL-6 may also have a proinflammatory role, as in advanced atherosclerosis.
- *Transforming growth factor- β* : Increased expression of TGF- β 1 RNA and protein expression has been seen after an ischemic stroke, especially in infarct border zones (Krupinski J 1996). Its expression in penumbra and in recovery phase of some CNS diseases suggests a neuroprotective function.
- *Interleukin-10*: In ischemic and hemorrhagic stroke cases, peripheral blood mononuclear cells are seen to secrete this neuroprotective cytokine (Van Exel E 2002). Studies have shown that lower IL-10 levels are associated with increased risk of stroke.
- *High mobility group protein-1 (HMG-1)*: It is a ubiquitous and abundant nuclear and cytoplasmic protein and a chromatin component in eukaryotic cells; which acts by binding to DNA, in addition to facilitating gene transcription and stabilizing the nucleosome structure. It is released and secreted by activated innate immune cells,

macrophages, monocytes and astrocytes, and can act as a proinflammatory mediator, and also acts to promote the release of other proinflammatory mediators (Kumar A 2008). Experimentally antiHMG1 antibodies have been used to counter its effect on ischemic injury.

- *Other cytokines*: Limited studies and evidence are available with interferon- γ (IFN- γ), IL-2, IL-4, IL-16, IL-17, and granulocyte-macrophage colony stimulating factor (GM-CSF) (Emsley HC 2002).

Chemokines

These polypeptides are generally smaller than cytokines, and have a role in cellular communication and inflammatory cell recruitment in host defense. Of these, IL-8 and monocyte chemo-attractant protein-1 (MCP-1), of the CXC and CC chemokine families, respectively, have been implicated in cerebral ischemia (Mennicken F 1999):

- *IL-8*: Studies have noted that patients with ischemic stroke have IL-8 mRNA expressing mononuclear cells in blood and elevated IL-8 in plasma, which possibly has a proinflammatory role in recruiting neutrophils. Overall, CSF levels are higher than plasma level, indicating its site of production in CNS (Kostulas N 1999). Interestingly, CSF levels of IL-8 tend to increase initially and then fall rapidly in large infarcts or gray matter infarcts suggesting a proinflammatory role, in contrast to constant elevated levels (for 3 months) in small white matter lesions suggesting a neuroprotective function (Tarkowski E 1999).
- *MCP-1*: Significant rise in acute ischemic stroke (proinflammatory) has been associated with monocyte/ macrophage infiltration (Losy J 2001).
- *Interferon- γ -inducible protein-10 (IP-10)*: In a recent study by Canoui-Poittrine et al. (Canoui Poittrine F 2009), it was observed that in healthy middle-aged men, higher systemic levels of chemokines like IP-10 and RANTES are most likely independent predictors of future ischemic stroke.
- *CC chemokine ligand-5 (CCL-5)/Regulated on Activation Normal T Cell Expressed and Secreted (RANTES)*: Aggregates of RANTES, a member of the CC chemokine family, that form on the cell surfaces have been reported to mediate through its receptor (CCR5), and act as powerful activators of leukocytes for promoting the directed migration of leukocytes into damaged or inflamed tissue (Appay V 2001, Backon KB 1995, Canoui Poittrine F 2009). It is produced by a variety of cells, including T-lymphocytes, platelets, endothelial cells, smooth muscle cells, and glial cells. A study by Terao et al. (Terao S 2008) strongly implicated this chemokine in the pathogenesis of experimental ischemic stroke, and suggested that the RANTES that mediates the cerebral inflammation, blood–brain barrier dysfunction, and tissue infarction is largely derived from circulating blood cells.

Nitric oxide and cyclooxygenase-2 (COX-2) Three NOS isoforms exist (Del Zoppo G 2000):

- Neuronal NOS: Harmful effects on ischemic stroke.

- Endothelial NOS: Beneficial effect, since it causes vasodilatation.
- Inducible or immunologic NOS (iNOS): Contributes to ischemic injury. Inhibition of iNOS reduces infarct volume in middle cerebral artery obstruction (MCAO), and it has been demonstrated in neutrophils and blood vessels in patients who died within 24 h of ischemic stroke (Forester C 1999).

Experimental cerebral ischemia have shown elevated COX-2 mRNA and protein, as well as toxic prostanoids and reactive oxygen species, secreted by microglia, at the border of the ischemic territory, and thought to exacerbate the effects of ischemia (del Zoppo G 2000).

Matrix Metalloproteinases (MMPs)

These are a family of proteolytic enzymes involved in extracellular matrix modeling, but may contribute to the neuroinflammatory response. Upregulation of MMP-9 in the acute phase, as compared to MMP-2 in chronic recovery stage reflects both deleterious and beneficial effects (Adibhatla RM 2008, Mun-Bryce S 1998). MMP, especially MMP-9 levels, have been associated with poor neurological outcome, infarct growth, and hemorrhagic transformation events (Montanner J 2001 and 2003, Ross A 2008).

Adhesion Molecules

Leukocyte interaction with vascular endothelium is mediated by three main groups of cell adhesion molecules: selectins (comprising P-selectin, E-selectin, and L-selectin); integrins (e.g., lymphocyte function-associated antigen-1, and Mac-1); and the immunoglobulin superfamily (which includes ICAM-1 and vascular adhesion molecule-1: VCAM-1) (DeGraba TJ 1998). These molecules not only enable leukocyte infiltration during acute stroke, but also have a role in pathogenesis of atherosclerosis and changes in atheromatous plaque. In the human brain, the expression of ICAM-1, VCAM-1, and E-selection of cerebral microvascular endothelial cells is increased by IL-1 β , TNF- α , and lipopolysaccharide. Localized ICAM-1 type is expressed in histologically normal human carotid bifurcation, a high-risk region for the development of atherosclerotic plaque, whereas endothelial ICAM-1 expression is increased in symptomatic versus asymptomatic carotid plaque. Serum levels of sICAM-1 (and E-selectin) are elevated in cerebrovascular (large and small vessel) diseases; becomes high after cerebral ischemia; and attains peak levels in 24 h of acute ischemic stroke. In contrast, sVCAM-1 elevates between days 1 and 5, and peaks at 5 days (Emsley HC 2002).

Neuropeptides

A number of neuropeptides have been implicated in the genesis of neurogenic inflammation, including substance P (SP), calcitonin gene-related protein (CGRP) and neurokinin A (Karaszkeski B 2009). Stimulation of the neuronal C-fibers by vanilloids, histamine or prostaglandins, among others, leads to neuropeptide release.

- *Neuropeptide Y (NPY)*: This modulates the immune cell distribution, T helper cell differentiation and natural killer cell activation. Studies have shown that NPY and its receptor Y1 partly mediate ischemic/reperfusion injury via upregulation of nNOS and eNOS, the effects of which can be controlled by NPY-Y1 receptor inhibition. NPY levels, in experimental studies, were found to be increased at 6 h in the peri-

ischemic region and peaked at around 3 days, decreasing at 10 days (Askalan R 2001).

- *Substance P*: Most potent of the neuropeptides. Is a member of the tachykinin family that also includes neurokinin A (NKA), neurokinin B (NKB) and neurokinin? (NK?) (Turner R 2007). These peptides are produced from preprotachykinin genes 1 and 2 (Campos MM 2000) SP potentially binds to three receptors (NK1, NK2, NK3) but has a higher affinity for the neurokinin 1 (NK1) receptor, which results in neurogenic inflammation, manifesting as increased vascular permeability, vasodilatation, tissue swelling and cell migration. Release of SP maybe one of the earliest pathophysiological events associated with injury to the brain, leading to release of inflammatory cytokines, free radical and endothelial nitric oxide (Persson MG 1991). SP is capable of regulating the action of other neurotransmitters, including dopamine and acetylcholine, and the opening of inward cation channels, in particular calcium. Levels of SP has been observed to be raised in ischemic stroke, while administration of an SP antagonist (SR-140333, nelpitantium besilate) significantly reduced infarct volume and improved neurological function measured at 24 h following ischemia (Karaszkeski B 2009).

Cellular Arm

The key components of this arm are blood derived leukocytes, which have a role in secondary brain damage in ischemic and reperfusion stages; while microglial cells, are the major CNS source of cytokines and other mediators, and also become phagocytes when fully activated by neuronal death.

Leukocytes

Elevated total leucocyte counts, independent of smoking, have been associated with higher incidence of vascular diseases and cerebral infarction. Various studies have shown that neutrophil accumulation starts within 6–12 h of onset, increases for 24 h, peaks in 48–72 h, and finally replaced by mononuclear cells in 4–6 days. This also correlates with CSF neutrophil levels (Akopoy SE 2006).

Microglia

Generally microglia is in a resting phase and constitutes 5% to 20% of glial population. During ischemia, depending on the time and extent, these get activated, and undergo substantial morphological and metabolic transformation, along with rapid and profound genetic upregulation. Subsequently they transform into the principal CNS source of cytokines like IL-1 β , TNF- α , and TGF- β (Gregerson R 2000).

Acute Phase Reactants and Body Temperature

In the normal condition body tends to respond to various tissue injury, including inflammatory and infective conditions, by means of cytokines, primarily IL-6 and IL-1. The classic acute phase reactants in cerebrovascular ischemia are C-reactive proteins (CRP), serum amyloid A protein, and fibrinogen.

C-reactive Protein

Healthy person normally has a median CRP concentration of approximately 1 mg/L, while during any tissue injury, inflammation or infection it tends to undergo 100-fold or more increase. Elevated CRP levels have been demonstrated to predict the risk of: (a) first ischemic stroke among apparently healthy men; (b) future ischemic stroke and TIA in the elderly; and (c) fatal stroke in the elderly. Studies have shown a very early increase (within 3 h) in patients with acute stroke with or without infection, and are an independent predictor of survival or nonfatal vascular event after ischemic stroke (Hu Z 2000, Rost NS 2001).

Erythrocyte Sedimentation Rate And Fibrinogen (ESR)

In cases of ischemic stroke, elevated ESR is an independent predictor of poor outcome within the first month, and early stroke recurrence (Belestrino M 1998). In contrast, fibrinogen, is an independent risk factor for stroke and significant hyperfibrinogenemia occurs in patients with acute cerebral infarction in association with leukocytosis and an increase in leukocyte aggregation (D'Erasmus E 1991, Belch J 1998).

Body Temperature

Studies on animal models revealed hypothermia of the brain and body had profound influence on stroke outcome, since it tends to reduce infarct size, unlike hyperthermia, which enhances neuronal damage (Yenari M 2008, Mi'nembres E 2008). Subsequent clinical studies have shown that body temperature has been independently and significantly related to initial stroke severity, lesion size, mortality, and outcome in survivors. Elevated body temperature in patients with acute stroke, possibly due to infections, has been associated with increased morbidity and mortality.

Role of Neuroimaging in Evaluation of CNS Inflammation in Stroke

Newer imaging techniques have enabled *in vivo* evaluation of cerebral inflammation, and subsequent correlation with neurologic outcome and brain tissue damage. These include gamma camera imaging of reinjected 111indium-labeled leukocytes (Pozzili C 1985) demonstrating neutrophilic infiltration within 24 h of acute cerebral infarcts; and technetium-99m hexamethylpropyleneamine oxime (99mTc HMPAO)-labeled leukocyte brain single-photon emission computed tomography (Wang PY 1993), showing neutrophilic accumulation with infected areas. PK11195 is a specific ligand for the peripheral benzodiazepine binding site. After cerebral ischemia, increased binding of PK11195 is colocalized with invading the cells of mononuclear-phagocytic lineage, in and around infarcted tissue. Presence of activated microglia can be demonstrated for weeks after onset of ischemic injury (Gerhard A 2000).

Proposed Interactions Unifying Various Pathophysiologic Mechanisms

A wide range of mechanisms has been proposed for unifying and linking inflammation, infection, atherosclerosis and vascular risk factors in the pathogenesis of stroke.

Inflammatory Mechanisms

Apparently inflammation, marked by raising CRP levels, is the pivotal point, which not only contributes to atherogenesis, but also contributes to plaque rupture, precipitating acute thromboembolic phenomenon, culminating in acute stroke. However, the interactions between these multiple factors are quite complex. CRP may be elevated in a number of cardiovascular risk factors like increasing age, smoking, body mass index, lipid levels, and hypertension, while hypertension it may have a proinflammatory role mediated by sICAM-1 and IL-6 (Pasceri V 2000).

It may also be elevated in response to other infective etiologies, and have a proinflammatory effect by modulating expression of adhesion molecules on vascular endothelium, with subsequent recruitment of monocytes and other immune cells. These, along with activated T-cells release various growth factors and cytokines, like TNF- α and IL-1, leads to advanced phase of atherosclerosis (Barath P 1990, Galia J 1996).

Procoagulant State

A prothrombotic state in various inflammatory and infectious conditions, with altered immune function, predisposing the large vessel to atherothrombosis and stroke. Modulation occurs due to reduced circulating antithrombotic activated protein C (APC), elevated C4b-binding protein, and a low ratio of tissue plasminogen activator to plasminogen activator inhibitor, or due to increased fibrin D-dimer levels, Cardiolipin immunoreactivity, and fibrinogen levels (Kumar A 2008, Ameriso SF 19991).

Evidence of continued endothelial damage is reflected by increased levels of vWF, while acute episodes are represented by raising CRP levels, which act in tandem with proinflammatory cytokines, like IL-6, to produce a procoagulant state, which act by the extrinsic pathway (Di Napoli M 2001). Procoagulant state precipitating occlusive cerebrovascular disease is encountered in a number of disease process:

- (a) SLE: Antiphospholipid antibodies like anticardiolipin antibodies and lupus anticoagulant acts by inhibition of prostacyclin formation, causing platelet aggregation; inhibition of prekallikrein, alterations of antithrombin III, decreased fibrinolysis, decreased release of plasminogen activator, inhibition of protein C activation, and the induction of endothelial injury and thrombotic thrombocytopenic purpura (Kumar A 2008, Kitagawa Y 1990).
- (b) Inflammatory bowel disease: Affected by hypercoagulability-related thrombosis, vasculitis, and consumption coagulopathy leading to hemorrhagic events (Lossos A 1995).
- (c) Bacteriemia and septicemia: Incidence of thromboembolism in infective endocarditis and in septicemia is 20% and 10%, respectively. Mechanisms of thrombosis responsible include reduced levels of antithrombin III, proteins C and S, increased platelet aggregation and adhesion, impaired fibrinolysis, and antiphospholipid antibody formation; apart from the effects of endotoxins,

Other bacterial toxins, and proinflammatory cytokines such as IL-1 and TNF α (Veltonen V 1993).

Vasculitis and Altered Circulation

Though atherothrombosis and atherothrombotic embolism are the commonest mechanisms for cerebrovascular occlusion, other less frequent causes include inflammatory vasculitis, like giant cell arteritis, Takayasu arteritis and Wegener granulomatosis; and infective pathology due to *Mycoplasma* infection, varicella zoster and neurosyphilis (Emsley HC 2002, Eskalan R 2001).

Vascular supply may be compromised in cervical artery stenosis, due to preexisting anomalies of extracellular matrix; or due to cardioembolism in a setting of systemic lupus erythematosus (SLE) with valvular heart disease.

For the above considerations and more, there is a compelling need to accelerate efforts to interrogate the stroke process and define the links that exist with other conditions such as vascular and neurodegenerative dementia. It is also crucial to expand the narrow repertoire of therapeutic opportunities for these devastating conditions. To accomplish this, novel approaches are required that expand upon our evolving mechanistic understanding of the fundamentals of cell survival and death processes as well as tissue repair. The future depends upon how successful we are in deciphering these mechanisms and bringing clarity to the complex interactions between the multiplicity of cell and tissue types within the brain (Lo, 2003). Armed with this knowledge and its successful therapeutic application, the field of stroke could be transformed.

Keeping in view this spirit, we will now try to address the selected issues fundamental to the science of ischemic stroke and vascular dementia. It begins with posing questions about stroke risk factors followed by a discussion of key cell and tissue mechanisms that render brain susceptible as well as tolerant to ischemic injury, including those promoting tissue protection and repair. The chapter ends by highlighting promising treatment strategies, inspired by these endogenous mechanisms, which present the opportunity to open new avenues in stroke therapy.

Stroke Risk Factors and Triggers

A stroke risk factor is a characteristic of an individual that increases the risk for stroke compared to someone without that characteristic (Hankey, 2006). Some risk factors cannot be modified, such as a family history of cerebrovascular diseases, older age, male sex, and Hispanic or Black race (Allen and Bayraktutan, 2008; Hankey, 2006). Other risk factors are modifiable, and their correction reduces the chance of having a stroke (Table 1). These factors, which often coexist, have been estimated to account for 60%–80% of stroke risk in the general population (Allen and Bayraktutan, 2008; Hankey, 2006). Genome-wide association studies are increasingly being employed to identify susceptibility genes for stroke (Hegele and Dichgans, 2010). Although several loci have been identified, the need for independent replication and the modest effect sizes have precluded the full assessment of the clinical relevance of these findings (Hegele and Dichgans, 2010).

Table 1. Major Modifiable Risk Factors for Ischemic Stroke

Classification	Risk Factor	References

^a Factors demonstrated in randomized clinical trials to reduce stroke risk if corrected, or for which a strong, consistent, and independent association with stroke has been established (Hankey, 2006).

^b Factors for which the association with stroke is less firm and/or no causative role has been established. WBC, white blood cells; CRP, C-reactive protein.

Risk Factors and Propensity to Stroke?

Risk factors have profound effects on the structure and function of blood vessels and on their interface with circulating blood. Many of the established risk factors alter the vascular structure by promoting atherosclerosis and stiffening of the arteries and by inducing narrowing, thickening, and tortuosity of arterioles and capillaries (Allen and Bayraktutan, 2008; Iadecola and Davisson, 2008). With the brain, these morphological changes are often associated with reductions in resting cerebral blood flow (CBF) and marked alterations in CBF regulation. Thus, aging, hypertension, diabetes, and hypercholesterolemia impair vital adaptive mechanisms that assure that the brain is adequately perfused (Arrick, 2007; Iadecola and Davisson, 2008; Iadecola, 2009; Kitayama, 2007). The ability of the endothelium to regulate microvascular flow is compromised, while the increase in blood flow evoked by neural activity is suppressed, resulting in a mismatch between the brain's energy supply and demand (Arrick, 2007; Iadecola and Davisson, 2008; Iadecola, 2009; Zou, 2004a).

Some risk factors, like hypertension and diabetes, impair protective vascular mechanisms that keep CBF stable during reductions in blood pressure (cerebrovascular autoregulation), facilitating the occurrence of ischemia if intravascular pressure drops (Immink, 2004; Kim, 2008). These vascular alterations increase the brain's vulnerability to ischemia after arterial occlusion because they compromise the development of collateral flow arising from adjacent nonischemic vascular territories, which is vital to the survival of the ischemic

perinfarct zone (see Parenchymal Failure Section). In addition to their vascular effects, some risk factors, like aging and diabetes, may enhance the intrinsic susceptibility of brain cells to injury, amplifying the tissue damage produced by ischemia (Biessels, 2002), but the biological bases of this effect are not well understood. Little is known about the interaction among the different stroke risk factors and whether their vascular effects are additive or synergistic. Furthermore, the relative contribution of parenchymal and vascular factors to stroke risk remains to be determined.

Cerebral Blood Vessel Alteration by Risk Factors?

Many cardiovascular risk factors increase the production of reactive oxygen species (ROS) and promote inflammation in systemic and cerebral blood vessels. The predominant vascular sources of ROS are the superoxide-producing enzyme NADPH oxidase, xanthine oxidase, mitochondrial enzymes, and uncoupling of nitric oxide synthase (NOS), a state in which this enzyme generates superoxide instead of NO (Faraci, 2006) (Figure 4).

Many of the damaging effects of oxidative stress on blood vessels are related to the biological inactivation of NO by the free radical superoxide, which reduces NO bioavailability and prevents its beneficial effects (Pacher, 2007; Schulz, 2008). Thus, loss of the vasoregulatory effects of endothelial NO leads to vasoconstriction and reduced NO-dependent vascular responses, with a negative impact on the regulation of microvascular flow (Schulz, 2008). Loss of the antiaggregant, antiproliferative, and anti-cell adhesion effects of NO promotes platelet aggregation, leukocyte adhesion to endothelial cells, and smooth muscle proliferation, key steps in vascular inflammation (Pepine, 2009; Zou, 2004b).

In addition, ROS can directly promote inflammation by increasing blood-brain barrier (BBB) permeability through upregulation of vascular endothelial growth factor (VEGF) and by inducing the expression of cytokines, matrix remodeling enzymes, including metalloproteases, and proinflammatory genes through NF κ B activation (Marchesi, 2008). One such NF κ B-dependent gene product, inducible nitric oxide synthase, produces large amounts of NO, which alter vascular structure and function through nitration and nitrosylation of critical proteins (Gunnnett, 2005; Guzik, 2003; Lima, 2010).

Peroxynitrite, a potent nitrating agent produced by the reaction of NO with superoxide, alters vasomotor reactivity by inactivating critical endothelial and smooth muscle enzymes and by activating the DNA repair enzyme poly-ADP-ribose polymerase (PARP), which leads to ATP depletion and vascular ion channel dysfunction (Pacher, 2007). Whereas ROS may set the stage for inflammation, vascular inflammation, in turn, leads to ROS production, creating a vicious circle that enhances vascular damage. Activation of the plasminogen system by oxidative stress and inflammation promotes matrix remodeling, smooth muscle cell migration, and intimal hyperplasia (Nicholl, 2006), factors that promote atherosclerosis and alterations in vascular structure. Thus, oxidative stress and vascular inflammation are major pathways through which risk factors exert their deleterious effects on blood vessels. However, it remains to be determined how individual risk factors trigger the activation of one or both of these processes. This is a critical question for targeting preventive strategies in patients with specific risk factors.

Figure4. Major Sources of ROS in Brain and Blood Vessels. Stroke risk factors and ischemia lead to the activation of several ROS-generating enzymatic systems. In ischemia, the increase in cytosolic Ca^{2+} activates the superoxide-producing enzyme NADPH oxidase (NOX), through PKC and NO derived from neuronal NOS (Brennan,2009; Girouard,2009). Mitochondria become depolarized by the Ca^{2+} overload (Nicholls, 2008) and, possibly, by ROS derived from NADPH located near the mitochondria (Girouard, 2009) producing large amounts of superoxide. The Ca^{2+} -induced activation of proteases and/or the pro-oxidant environment convert xanthine dehydrogenase (XDH) to xanthine oxidase (XO) (Abramov,2007), a superoxide-generating enzyme involved in purine degradation. Finally, the substrate deprivation induced by ischemia and the oxidative inactivation of essential cofactors like tetrahydrobiopterin (BH4) uncouple L-arginine oxidation from NO formation by NOS, resulting in superoxide production (NOS uncoupling) (Förstermann, 2010). Other potential sources of ROS include enzymes for arachidonic acid or catecholamine metabolism, but their participation in stroke-induced oxidative stress remains in question (Adibhatla and Hatcher, 2010; Kunz,2007a).

ROLE OF STROKE TRIGGERS

While vascular risk factors increase the likelihood of stroke in affected individuals, precipitating factors that act as “stroke triggers” must also be postulated. In some patients, the specific event responsible for the arterial occlusion can be identified, e.g., neck trauma leading to dissection and occlusion of the Table 1. In most instances the factors precipitating the ischemic event cannot be established. Although systemic infections, pregnancy and puerperium, use of illicit drugs, and mental stress often trigger a stroke (Elkind, 2007), precisely how these factors exert their effect remains unclear. Exacerbation of vascular inflammation and activation of the coagulation cascade are likely to play a role (Welsh,2009). For example, the added vascular dysfunction and blood clotting abnormalities, superimposed on those induced by stroke risk factors, could precipitate vascular occlusion or hemodynamic insufficiency. This view is supported by the fact that acute stroke often occurs in the setting of increased circulating leukocytes and elevated plasma markers of systemic inflammation and vascular activation, which also predict a poor outcome (Elkind, 2007; Welsh,2009). Thus,

our understanding of stroke triggers is limited, and mechanistic studies addressing these issues would be valuable in the identification of high-risk cases.

Parenchymal Failure: Brain death during Ischemia?

Because of its high intrinsic metabolic activity and large concentrations of the neurotransmitter-excitotoxin glutamate (Choi, 1992), the brain is especially vulnerable to ischemic insult. This can develop either as a consequence of thrombosis in situ or following embolic occlusion of a cerebral blood vessel, the latter usually arising from the heart or atherosclerotic plaques in the carotid artery and aortic arch. Although neurological dysfunction occurs within seconds to minutes of vessel occlusion, the evolution of ischemic injury and cell death continues in stages for minutes, hours, and even days, depending, in part, upon the vulnerability of the particular brain region, its cellular constituents, and the extent of residual perfusion.

The responses of blood vessels and their perfusion are important to the outcome as well. For example, a deficiency of vasodilating molecules such as endothelial NO enlarges the stroke size (Huang, 1996). Early restoration of blood flow by clot lysis and reperfusion decreases ischemic injury, and this may be achievable by giving recombinant tissue plasminogen activator (tPA), the only FDA-approved treatment for reestablishing flow and salvaging brain tissue. However, tPA is used in <10% of patients and even less frequently after 3 hr because of the risk of hemorrhage into ischemic tissue (NINDS tPA Study Group, 1995). Moreover, tPA may have other unintended risks (Kaur, 2004), such as injury to the blood-brain barrier by activating matrix metalloproteinases (Wang, 2003) or excitotoxicity in experimental models (Nicole, 2001). Combination therapies that ameliorate these effects may extend the tPA's therapeutic window while mitigating the untoward effects of reperfusion and plasminogen activation (Liu, 2004; Cheng, 2006; Murata, 2008). Theoretically, that could prolong tissue viability for hours or even longer, depending upon the rapid delivery of drug to the compromised brain (Ginsberg, 2008). Whether or not the vulnerable brain tissue can be rescued or protected after a protracted time period in the absence of partial or complete restoration of blood flow is an unanswered question. In all likelihood, areas of vulnerable brain do remain viable for hours after vessel occlusion, at least in some instances. For example, the hemiparesis that follows middle cerebral artery occlusion in the baboon was reversed in 73% of animals with reperfusion at 2–4 hour, compared to 33% and 17% in animals with reperfusion at 8 and 16–24 hour, respectively (Marcoux, 1982; Crowell, 1981; Jones, 1981). The challenge then is to restore adequate blood flow quickly after vessel occlusion and to protect viable tissue from unleashing mechanisms that lead to cell and tissue demise.

Salvageable versus Non-salvageable Tissue as Target for Therapy: Tissue distal to an occluded blood vessel is often heterogeneous, meta-stable, and differentially susceptible to ischemic injury. This meta-stable zone, termed the ischemic penumbra or the perinfarct zone (Astrup, 1981), is characterized by significantly depressed tissue perfusion that is barely sufficient to support basal ATP levels and oxygen metabolism as well as normal ionic gradients in the presence of electrical silence and suppressed protein synthesis. The ischemic penumbra, then denotes an “at risk” region that is functionally impaired but potentially salvageable. However, unless perfusion is improved or cells made relatively more resistant to

injury, the tissue at risk dies within a few hours (Lo, 2008a, 2008b). The ischemic core by contrast, refers to the irreversibly damaged tissue distal to an occluded blood vessel, characterized by <20% of baseline blood flow levels, depleted ATP stores, and irreversible failure of energy metabolism (Lo, 2008b). With time, the infarct core expands into the ischemic penumbra, and therapeutic opportunity is lost. Therefore, detecting a penumbra in patients can help to identify those who might benefit most from acute treatments that restore blood flow (thrombolysis or endovascular clot retrieval) or treatments for the future that render viable brain more resistant to ischemic injury. For this purpose, magnetic resonance imaging methods such as perfusion-weighted and diffusion-weighted imaging are most often used. Perfusion-weighted imaging measures the spatial extent of blood flow compromise, whereas diffusion-weighted imaging is thought to detect the region of attenuated diffusion of water, a putative surrogate marker for severely damaged brain tissue. The difference is thought to reflect the ischemic penumbra (Figure 2) (Ebinger, 2009). Although the predictive value of this method is still debated, perfusion-diffusion mismatch provides a useful first attempt to define the tissue at risk.

Prominent Mechanisms Leading to Cell and Tissue Demise in Stroke?

Within the ischemic penumbra, multiple mechanisms have been identified over the past few decades that irreversibly damage brain tissue (Figure 5). Understanding the contribution of each informs us about potential therapeutic opportunities and treatment targets. In the area of severely limited blood supply, ATP utilization continues in the presence of minimal synthesis and levels drop, leading to acidosis and loss of ionic homeostasis. As a consequence, cells swell and membranes rupture. However, ischemic cell death cannot be equated with limited ATP availability; rather, tissue death develops as a consequence of numerous ionic, biochemical, and cellular events that impose overwhelming stresses upon already compromised tissue (Dirnagl, 1999; Lo, 2003).

Causes of White Matter Damage Underlying Vascular Cognitive Impairment VCI?

In the cerebral autosomal-dominant arteriopathy with subcortical infarct and leukoencephalopathy (CADASIL syndrome), a monogenic disease associated with dementia, extensive white matter damage is caused by notch-3 mutations in vascular smooth muscle leading to vascular insufficiency (Chabriat, 2009).

In common forms of lacunar disease, however, the mechanism of the white matter damage remains unclear, although family history, hypertension, diabetes, and chronic smoking are well established risk factors (Selnes and Vinters, 2006). The white matter lesions consist of demyelination, axonal loss, enlarged perivascular spaces, astrogliosis, and microglial activation (Fernando, 2006; Pantoni and Garcia, 1995). The wall of arterioles is thickened by accumulation of hyaline material (lipohyalinosis) or completely disrupted (fibrinoid necrosis), leading to microhemorrhages (Fisher, 1968; Pantoni and Garcia, 1995). Capillary density, resting CBF, and cerebrovascular reactivity is reduced both in normal and affected white matter (Brown, 2007; Mandell, 2008; O'Sullivan, 2002).

Figure 5. The Ischemic Penumbra. The ischemic penumbra represents compromised, but viable brain tissue lying distal to an occluded blood vessel. The top three MR images in this figure were taken in the same patient early after occlusion of the middle cerebral artery. The images are shown in the horizontal plane passing through the lateral ventricles. “Stunned, but not dead tissue” is detected by magnetic resonance imaging (MRI) techniques that assess (1) the spatial extent of the perfusion or blood flow deficit that presents as red and yellow areas on perfusion-weighted imaging (PWI, top middle image) and (2) severely damaged tissue in the ischemic core that presents as high-intensity areas on diffusion-weighted imaging (DWI, top left image) (Ebinger, 2009). In this patient, the perfusion deficit is larger than diffuse lesion. The top right image depicts the mismatch between core areas with a diffusion lesion (dark blue) and the larger areas with low perfusion (light blue-green). Over hours to days (see text), the core territory expands due to the complex cascades involving excitotoxicity, oxidative stress, programmed cell death mechanisms, and inflammation, as the initial trigger of energy failure ultimately progresses to infarcted tissue. The resulting infarct is shown in the image at the bottom of the figure and is about the size of the initial perfusion deficit in this untreated patient. In later stages, some patients may also partially recover, in part due to endogenous mechanisms of repair and remodeling (Chopp, 2007). MRI scans courtesy of G. Albers, Stanford.

Disruption of the arteriolar wall by amyloid, as observed in genetic or sporadic forms of cerebral amyloid angiopathy and in AD, is also associated with white matter lesions (Weller, 2009). Hypoxia-inducible genes and markers of endothelial activation are unregulated, suggesting hypoxia-ischemia (Fernando, 2006).

A causative role of hypoxia-ischemia is also suggested by the fact that the blood supply to the subcortical and basal ganglia white matter is provided by terminal arterioles located on the watershed between two vascular territories: perforating arteries from the neocortex and penetrating branches arising from larger arteries at the base of the brain (Iadecola, 2009). Therefore, these areas may be particularly susceptible to vascular insufficiency, especially if the structure of the arterioles and their vasomotor function are altered. On the other hand, energy and blood flow requirements of white matter are much lower than those of gray matter, rendering the tissue, in theory, less vulnerable to anorexia-ischemia (Hertz, 2008). Therefore, alternative mechanisms leading to an increased intrinsic vulnerability to injury may also play a role. For example, risk factors for dementia could enhance white matter susceptibility to anorexia, as aging has been described to do (Baltan et al., 2008). Disruption of the BBB, an early event in leukoaraiosis, could lead to injury by producing perivascular edema, microhemorrhages, and inflammation, contributing to demyelination (Farrell and Wardlaw, 2009). Demyelinated axons may be more susceptible to ischemic injury due to their heightened metabolic requirements caused by loss of energy-efficient salutatory conduction and leaky sodium channels (Trapp and Stys, 2009). Furthermore, dysfunction within the endothelium may compromise the trophic effect that these cells exert on neurons and glia, contributing to brain dysfunction and damage (see section on repair mechanisms). Aging, inflammation, hypoxia and, possibly, other risk factors can also reduce the repair potential of the damaged white matter by impairing oligodendrocyte progenitor recruitment and differentiation (Back, 2002; Pang, 2010; Sim, 2002). Therefore, the mechanisms underlying leukoaraiosis might be distinct from those of ischemic cell death and are a fertile ground for new investigations.

Stroke and Dementia?

The major mechanisms of tissue dysfunction and death cited above develop as a consequence of acute vessel occlusion and the attendant activation of endogenous mechanisms of cell injury and tissue demise. More subtle and less well understood mechanisms are beginning to define a new research frontier linking cerebrovascular dysfunction and small strokes to the development of vascular cognitive impairment (VCI) and Alzheimer's disease (AD), the most common causes of dementia (Fotuhi, 2009). AD and "vascular" dementia have traditionally been considered distinct entities (Iadecola, 2004). Thus, AD, the most prevalent of the two, is characterized pathologically by deposition of the amyloid β peptide (Ab) in the brain parenchyma (amyloid plaques) and blood vessels (amyloid angiopathy) and by neurofibrillary tangles (Querfurth and LaFerla, 2010). On the other hand, cerebrovascular diseases can lead to cognitive impairment in different ways. For example, a single stroke can cause dementia by damaging brain regions critical for cognition (strategic infarct dementia), while multiple strokes can cause stepwise cognitive deterioration through cumulative brain damage (multi-infarct dementia) (Leys, 2005; Pinkston, 2009). Most often, VCI has been due to small white matter lesions (leukoaraiosis) that are thought to

interrupt neural pathways involved in cognition (Pinkston, 2009). A recent realization has been that AD and cerebrovascular diseases coexist in up to 60% of cases (Leys, 2005; Pinkston, 2009). Thus, although cases of “pure” AD and vascular dementia can exist, in most cases the cognitive decline can be attributed to overlapping cerebrovascular and AD pathologies (Querfurth and La-Ferla, 2010). The causes of leukoaraiosis and the overlap between AD and cerebrovascular diseases are discussed in the next sections. Stroke doubles the risk of developing dementia (Leys et al., 2005). Although, as discussed above, location, size, and number of ischemic lesions, as well as leukoaraiosis can account for the cognitive impairment in some cases, epidemiological and pathological evidence indicates that stroke also increases the risk for AD. Alzheimer pathology can facilitate the development of dementia in patients with ischemic injury, and, vice versa, ischemic injury can aggravate the cognitive deficits induced by AD (Fotuhi, 2009). These findings have suggested a previously unrecognized interaction between amyloid pathology and ischemic injury. This is not surprising, considering that Ab has powerful cerebrovascular effects. Ab constricts cerebral vessels, suppresses vascular reactivity, and impairs autoregulation, leading to vascular insufficiency and increased susceptibility to ischemic injury (Iadecola, 2004; Zhang, 1997).

Conversely, ischemia and hypoxia can induce Ab accumulation by promoting its cleavage from APP (Tesco, 2007) and by downregulating the lipoprotein-related receptor protein-1, a critical receptor in the vascular clearance of Ab (Bell et al., 2009; Tesco, 2007; Wu, 2005). Therefore, in a vicious cycle, the vascular effects of Ab aggravate ischemia, and, in turn, brain ischemia enhances Ab accumulation (Iadecola, 2004). Recent studies have also linked plasma Ab to the white matter damage underlying leukoaraiosis (Gomis, 2009; Gurol, 2006). The significance of this finding and its underlying mechanisms remain to be defined and placed in context with other findings showing that Ab could promote axonal injury directly through its cytotoxic effects (Querfurth and LaFerla, 2010) or indirectly by inducing vasoconstriction and ischemia (Iadecola, 2004). Therefore, the vascular dysfunction induced by circulating and parenchymal Ab may act in concert with the structural and functional vascular changes induced by the risk factors to amplify the vascular insufficiency in small white matter arterioles leading to white matter injury. However, factors other than Ab could also contribute to the interplay between AD pathology and cerebrovascular diseases. For example, cerebral arterioles of AD patients exhibit a tendency to constrict due to increased activity of transcription factors (serum response factor/myocardin) that control the expression of contractile proteins in smooth muscle cells (Chow, 2007). This finding may play a role in the increased vasoconstrictor tone and reduced CBF observed in AD (Iadecola, 2004). It remains to be established whether these changes in gene expression are related to Ab or to upstream molecular events independent of it.

BRAIN REPAIRMENT AFTER STROKE

A well-known fact, in clinical stroke is that most patients show some degree of recovery over time. As the brain recovers, considerable reshaping of cortical areas takes place. Functional MRI studies demonstrate that peri-infarct areas are highly dynamic (Dijkhuizen, 2003; Chopp, 2007). Representational areas shift as latent networks are unmasked and parallel circuits are recruited adjacent to damaged regions (Murphy and Corbett, 2009). More

recently, advanced optical imaging techniques combined with Electrophysiology demonstrated that this remodeling at a circuit level can be correlated with specific processes of dendritic and synaptic plasticity at a cellular level (Li and Murphy, 2008). Imaging of mitochondrial function (Liu and Murphy, 2009) and vascular dynamics (Schaffer, 2006) has provided new insight into how the brain responds to microvascular perturbations following ischemia. These powerful tools may eventually allow one to interrogate mechanisms of stroke recovery at a molecular and cellular level while testing pro recovery therapies and strategies (Murphy and Corbett, 2009; Zhang and Chopp, 2009). Repair and remodeling processes after stroke; A major advance within this past decade has been the realization that adult mammalian brains also exhibit focal areas of ongoing neurogenesis in the subventricular zone and subgranular zone. Under normal conditions, these newborn neurons migrate to olfactory regions and hippocampus. But after cerebral ischemia or hemorrhage; the birth of new cells seem to increase and neuroblasts reroute toward damaged brain tissue (Arvidsson, 2002; Parent, 2002); perhaps as part of an endogenous attempt by the brain to repair itself. However, whether these new neurons significantly contribute to functional recovery remains unclear. Neurogenic responses may persist for surprisingly long periods of time, but the majority of these newborn cells survive only for a few days (Arvidsson, 2002). Whether these cells develop normally, express neurotransmitters, or even integrate into existing neural networks remains to be fully elucidated. Future attempts to promote endogenous neurogenesis for therapeutic purposes will have to address ways to modify parenchymal micro-environments to enhance neuronal survival and integrate newly born cells into viable circuitry. In concert with neurogenesis and neural plasticity the brain recovering from stroke exhibits complex patterns of vascular remodeling. Angiogenesis and vasculogenesis in perinfarct regions have been detected in rodent models of cerebral ischemia (Ding, 2008) as well as in human stroke (Krupinski, 1996). Indeed, it is now recognized that angiogenic and neurogenic responses are tightly coregulated after stroke and brain injury (Arai, 2009). This might not be surprising, because molecular mechanisms of neurogenesis and angiogenesis have been evolutionarily conserved so that similar mediators and pathways are involved in both phenomena (Carmeliet and Tessier-Lavigne, 2005). In the normal brain, the neurovascular niche defines these complex mechanisms of cell-cell signaling between cerebral endothelial and neural precursors in the subventricular and subgranular zones of ongoing neurogenesis. In the context of poststroke recovery, these close relationships between neurogenesis and angiogenesis are maintained. Neuroblasts migrate along perivascular routes (Thored et al., 2007). Promotion of neurogenesis enhances vascular regrowth and, conversely, angiogenic stimulation enhances neurogenesis (Ohab, 2006; Taguchi, 2004). Hence, it seems likely that brain recovery after stroke comprises interdependent neurovascular plasticity and remodeling processes that recruit multiple common mediators and signals (Snappyan, 2009). The new frontier of neurovascular repair may require a detailed exploration of how these multi-cell and multi-signal phenomena are regulated in the context of stroke. Recent experimental studies have suggested that pharmacological interventions such as EPO, statins, activated protein C, and phosphodiesterase inhibitors may promote functional recovery after cerebral ischemia (Wang, 2004; Zhang, 2006; Thiagarajan, 2008; Chen, 2009). Ultimately, therapies that can augment these endogenous signals and substrates of neurovascular remodeling may have long therapeutic time windows in stroke (Zhang and Chopp, 2009).

Implications for Therapeutic Intervention beyond Thrombolytics

Current protocols of primary stroke management and secondary prevention focuses on modifiable vascular risk factors such as hypertension, smoking, carotid stenosis, atrial fibrillation, physical inactivity, diabetes mellitus, and dyslipidemia, with usage of drugs like antiplatelet agents, anti-hypertensive drugs, lipid-lowering agents, and anticoagulant drugs. A recent addition to this armamentarium was intravenous tissue plasminogen activator in cases of acute ischemic stroke, the efficacy of which is often limited by stroke severity, older age, systolic hypertension, location of arterial occlusion, collateral blood supply, and time from stroke onset to treatment, and reperfusion-associated inflammation (Pandian JD 2009, Adibhatla RM 2008 and 2009). The overall re-canalization rate in thrombolytic therapy varies from 46.2% during the first 6–24 h of intravenous administration, to 63.2% in intraarterial and 83.6% with mechanical reperfusion techniques (Pandian JD 2009). Current understanding of various patho-genetic mechanisms of stroke has paved the path for newer therapeutic approaches.

Currently Available Agents with Anti-Inflammatory Role

Commonly used agents like the anti-platelet agent acetylsalicylic acid (aspirin) and the lipid-lowering agent's β -hydroxy- β -methylglutaryl coenzyme A reductase inhibitors (statins) possess anti-inflammatory effects in addition to their traditionally accepted actions.

Aspirin: Apart from its well-established role in prevention of death, myocardial infarction, and stroke in high-risk patients, aspirin has a direct role in modifying CRP levels, thus raising the possibility of an anti-inflammatory action apart from its *anti-platelet* effect mediated via COX inhibition. Based on the findings of the Second European Stroke Prevention Study (ESPS-2), and European/Australian Stroke Prevention in Reversible Ischemia Trial (ESPRIT); a combination of aspirin and extended-release. Dipyridamole was found superior to aspirin alone in reducing the occurrence of the primary combined end point of vascular death, nonfatal stroke, nonfatal myocardial infarction, and major bleeding complications, and found favor with the most recent American Heart Association guidelines. This was partly attributed to the anti-inflammatory actions of this combination therapy (Weyrich AS 2009). Further, it is also thought to block NF- κ B, which is the transcription factor for a host of proinflammatory mediators of ischemia. Since NF- κ B also has a role in the resolution of inflammation, excessive modulation might create a problem during the recovery phase (Grilli M 1996).

Statins: *Lipid-lowering effect* of statins has already established its efficacy by significantly reducing the incidence of ischemic stroke in patients with coronary artery disease, both with and without elevated serum cholesterol concentrations (Crouse JR 1998).

Anti-inflammatory and/or neuroprotective properties of statins: Statins have found its base in their ability to reduce CRP levels, especially ones with high CRP levels (Di Napoli M 2001). Its efficacy has been demonstrated by measuring the intimal–medial thickness on carotid ultrasound, an indicator of atherosclerotic disease. It has also been reported that statins achieve atherosclerotic plaque stabilization or even regression by reducing macrophage activation within the vessel wall, inhibition of MMP-induced plaque rupture, and prevention of cytokine-mediated smooth muscle cell proliferation, whereas reduction in serum cholesterol encourages an antithrombotic state, by reducing platelet aggregation or by lowering plasminogen activator inhibitor-1 levels (Mohler ER 1999). It also has a

neuroprotective action by upregulation of endothelial NOS and inhibition of iNOS, an effect associated with the augmented cerebral blood flow and reduced infarct size, reduction of leukocyte–endothelium interaction, modulation of CNS cytokine production, and antioxidant effects.

Recently, a Stroke Prevention by Aggressive Reduction in Cholesterol Levels study showed that treatment with high dose atorvastatin reduced risk of stroke in patients with recent stroke and transient ischemic attack and no known coronary artery disease (CAD) (Gedikli O 2008).

Angiotensin converting enzyme inhibitors and angiotensin II receptor blockers: The effects of these agents have been observed to reach beyond the known blood pressure lowering action mediated by the renin–angiotensin–aldosterone axis. Angiotensin II has proinflammatory effects via augmentation of expression of VCAM-1, MCP-1, and IL-6, and increased production of reactive oxygen species, which can be countered by angiotensin converting enzyme inhibitors or angiotensin II receptor blockers for having anti-inflammatory effect (Libby P 2001).

Novel Therapeutic Agents with Anti-Inflammatory Role

Neuroprotective agents: This includes a diverse range of drugs directed at restricting damage and salvaging the penumbral tissue. Though the small rim of penumbra acts as a barrier to the successful application of these drugs, their role can be vital in a setting where reperfusion obtained by combined thrombolysis and neuroprotective agent, is sufficient. These drugs act by modulating the excitatory amino acid system, controlling calcium influx, or can be metabolic activators, antiedema agents, inhibitors of leukocyte adhesion, and free radical scavengers. Unfortunately, despite the safety and efficacy being proved by more than 100 clinical trials its translation into clinical practice remains awaited (Lebs Kind DS 2001).

- **Free radical scavenger:** Edaravone is the first clinical drug for neuroprotection in the world which has been used from 2001 in most ischemic stroke patients in Japan, and is especially useful in thrombolytic therapy with tissue plasminogen activator (tPA) (Abe K 2008).
- **Gene therapy:** Neural stem cell (Abe K 2008) could provide a future regenerative potential against ischemic brain damage at chronic stage.
- **Inhibiting apoptotic mechanism:** Brain parenchyma under threat of infarction contains neuronal cells, which undergo caspase-dependant (either by the caspase-3-dependant intrinsic pathway, originating from mitochondrial release of cytochrome c; or caspase-8-dependant extrinsic pathway, originating by the activation of cell surface death receptors) apoptosis, as well as non-neuronal cells which undergo non-caspase-dependent apoptosis. Current studies are directed towards therapeutic intervention of these potentially salvageable areas (Broughton BR 2009, Yuwan J 2009).
- **Ischemic preconditioning and inhibition of oxygen sensors; Ischemic postconditioning:** The rationale behind this strategy is downregulation of cellular and tissue metabolism (Yenari M 2008), which is similar to that of hypothermia

(Minembres E 2008) to overcome the effects of ischemia. Further studies have described a new family of oxygen sensors—including prolyl hydroxylase domain-containing proteins 1-3 (PHD1-3)—which possibly has a role in balancing hypoxia tolerance, ischemic preconditioning and inflammation, and thus provide a novel setting for newer pharmacological interventions for ischemic and inflammatory diseases (Fraisl P 2009). Ischemic postconditioning was initially referred to a stuttering reperfusion and has been performed immediately after reperfusion, for preventing ischemia/reperfusion injury in both myocardial and cerebral infarction. It can be induced by a broad range of stimuli or triggers, and may even be performed as late as 6 h after focal ischemia and 2 days after transient global ischemia. Ischemic preconditioning or partial/gradual reperfusion, provides insights into the protective mechanisms of reperfusion injury and the acute, mitogen-activated protein kinase (MAPK), protein kinase C (PKC), and ATP-sensitive K⁺ (K(ATP)) channel cell signalling pathways (Edyinson L 2009, Tanahashi N 2009).

- **Hyperbaric oxygen therapy:** Hyperbaric (HBO) or normobaric oxygen (NBO) therapy applied in acute ischemic stroke aims to salvage irreversible tissue damage by supplying oxygen to the ischemic area. Oxygen delivered at higher pressures (2.5–3 ATA) within initial few hours appears more promising for bridging of a transient ischemic period until reperfusion of the penumbra takes place, and has shown to reduce infarct size from 30–40%. Recent studies have demonstrated that physical oxygen therapy indeed improves oxygen supply of the ischemic penumbra as well as the cellular bioenergetic metabolism. In this mechanism, the mitochondria, including their role in apoptotic cell death pathways as well as the modification of the cellular hypoxia sensor HIF-1 α are considered as potential “downstream pathways” of oxygen therapy (Poli S 2009).
- **Peroxisome proliferator-activated receptor-gamma (PPAR γ):** PPARs are ligand-activated transcription factors that control lipid and glucose metabolism. These have a role in gene expression, as well as may modulate gene transcription by directly interfering with other transcription factor pathways in a DNA-binding independent manner. Though all three isoforms (alpha, beta/delta, and gamma) are activated by the ischemic cascade, PPAR- γ , was shown to prevent post-ischemic inflammation and neuronal damage in several *in vitro* and *in vivo* models, and negatively regulating the expression of genes induced by ischemia/reperfusion (I/R). This may further be exploited for designing novel therapeutic targets (Collino M 2008).
- **Pituitary adenylate cyclase-activating polypeptide (PACAP) and vasoactive intestinal peptide (VIP):** Ischemic stroke not only leads to tissue degeneration, but also activates neuroprotective cellular mechanisms by releasing PACAP and VIP. These neuropeptides are widely distributed in both the central nervous system and peripheral organs of various vertebrates. They display pleiotropic biological activity and mediate via many intracellular pathways, with four categories of action: antiapoptotic, anti-inflammatory, metabolic, and modulation of gene expression. There are two structurally distinct receptors that recognize VIP peptides and PACAP with similar affinities (PACAP/VIPR-1, PACAP/VIPR-2), as well as a specific receptor for the PACAP peptide (PACAP-1). VIP has a wide physiological profile. In the periphery, VIP receptors are distributed throughout the gastrointestinal tract and genitourinary system, other smooth muscles and secretory glands and induce

relaxation in smooth muscle. VIP inhibits secretion in certain tissues, but stimulates secretion in others; and modulates activity of cells in the immune system.

In the CNS, VIP receptors are found abundantly in the cortex, hippocampus and thalamus, and have a range of both excitatory and inhibitory actions. All VIP receptors activate adenylyl cyclase (Wei Y 1996). Animal models confirm that the synthetic derivatives of these neuropeptides have considerable neuroprotective and anti-inflammatory potential, suggesting a possibility of their use as new therapeutic strategies in stroke management (Jo' zwaik-Bebenista M 2008).

- **Nuclear enzyme poly(ADP-ribose) polymerase 1 (PARP-1):** As discussed earlier, reactive oxygen and nitrogen species, including the reactive oxidant peroxynitrite, are generated in parenchymal, endothelial, and infiltrating inflammatory cells during ischemic stroke, and also during the reperfusion phase. These induce oxidative DNA damage and cause activation of the PARP enzyme family, which leads to depletion of its substrate NAD(+), slowing the rate of glycolysis, electron transport, and ATP formation, eventually leading to functional impairment or death of cells, as well as upregulation of various proinflammatory pathways. Animal model studies have shown significant therapeutic benefits of PARP inhibitors, which have entered clinical development for the experimental therapy (Pacher P 2008).
- **Induced hypothermia** is another strategy gaining popularity since it may limit the final extent of cerebral infarct. Though paracetamol has shown to decrease body temperature in acute stroke, however its efficacy needs further validation (Minnemans E 2008, Dippel DWJ 2001).
- **Minocycline in combination with tPA:** In an experimental study on spontaneously hypertensive rats, which were subjected to embolic focal ischemia using homologous clots and treated with combined minocycline at 4 h plus tPA at 6 h, it was noted that there was a decrease in plasma MMP-9 levels, reduction of infarction, and amelioration of brain hemorrhage. It was thus concluded that combination therapy with minocycline may extend tPA treatment time windows in ischemic stroke (Murata Y 2008).
- **Others:** Other therapeutic strategies are based on the neuroprotective action of erythropoietin (Maise K 2008), melatonin (Reiter RJ 2007), estrogen (Lebesgue D 2009), NOS inhibitors (del Zoppo G 2000, Bath PM 2002), and anti-high mobility group box 1 (HMGB1) monoclonal antibody (mAb) by altering permeability of the blood-brain barrier, expression of TNF- α , iNOS and MMP-9 (Mori M 2009).

Antimicrobial drugs and vaccines: Antichlamydial antibiotics also act by suppressing reactivation of chronic inflammation within atherosclerotic plaques, and have a potential role in secondary prevention (Grayston JT 1999). Influenza vaccine has been reported not only to reduce viral infection, but also secondary bacterial infections. A recent study has found a negative association between influenza vaccine and brain infarction, particularly in under 75 years population (Lavalley P 2002).

Antileucocyte agents: The deleterious effects of leucocytes in an ischemic setting have prompted the use of monoclonal antibody to competitively block its adhesion to ICAM-1, and thus limit the extent of damage, and also extend the therapeutic window, during which

thrombolytic therapy may be administered. Due to adverse outcome in the first human trial with anti-ICAM-1 murine monoclonal antibody, other strategies have been sought, viz. Antineutrophil serum and antineoplastic agents to achieve neutrophil depletion (Enlimomab Stroke Group 2001).

Cytokine targets: Dual, anti-inflammatory and proinflammatory, effects of TNF- α and of IL-6, have been the primary concern in using strategies directed against these *cytokines*. In contrast, IL-1ra directed against IL-1, has found favor with patients with rheumatoid arthritis, and also in cases of acute stroke (Kostulas M 1999, Emsley HC 2008).

Vitamins: Studies have shown that a diet rich in fruits and vegetables has a lower cardiovascular risk, possibly due to antioxidant nutrients: vitamin C, beta-carotene and vitamin E. These might reduce atheroma formation by inhibiting oxidation of LDL (Matsui T 2001). Homocysteine, a sulfur-containing amino acid, is a demethylation product of dietary methionine, which is converted to cysteine by cystathionine B-synthase (a vitamin B6-dependent enzyme), or is remethylated by methionine synthase. The latter reaction is vitamin B12 dependent and requires 5-methyl-tetrahydrofolate, a product of folic acid metabolism that uses methylene-tetrahydrofolate reductase (MTHFR). Defects of cystathionine B-synthase and MTHFR and deficiencies in folic acid, B12, and B6 can lead to raised levels of homocysteine, which have been associated with cardiovascular disease and stroke. Mechanism of homocysteine causing vascular damage include impairment of endothelial functions, endothelial desquamation, oxidation of LDL, increased monocyte adhesion to the vessel wall, impaired vascular response to nitric oxide, and thrombotic tendency mediated by activation of coagulation factors and platelet dysfunction (Matsui T 2001). Studies have shown a correlation between ischemic cerebrovascular disease with MTHFR genotype and serum homocysteine concentration and an interaction with serum folate concentration. Others have also reported association of MTHFR A677V allele with severe carotid stenosis, a moderately elevated homocysteine after methionine loading with increased risk of ischemic stroke in young adults, a graded association of increasing plasma homocysteine with ischemic stroke caused by large-artery atherosclerosis and to a lesser extent small artery disease, an association with risk of silent brain infarction, an association with cervical artery dissection, and microvascular stroke (Sculz JB 1999). However, in contrast cross-sectional and case-control studies, prospective studies generally show less or no predictive ability for plasma homocysteine in coronary disease and stroke.

Predictive Role of Blood Biomarkers in Ischemic Stroke

A recent study reviewed the Medline and EMBASE from 1966 to January 2007 for studies of blood markers in patients with ischemic stroke and an assessment of outcome (death, disability, or handicap). Though cardiac markers showed the most consistent association with poor outcome, many studies were subject to bias. Although some markers had some predictive ability, none of the studies showed any added advantage of biomarkers over a validated clinical model. Thus the clinical usefulness for predicting prognosis in the setting of ischemic stroke is yet to be established, prior to being incorporated into any regimen (Whiteley W 2000).

CONCLUSION

The complex pathophysiology of a stroke encompasses various excitotoxicity mechanisms, inflammatory pathways, oxidative damage and ionic imbalances. Despite significant therapeutic advances in the form of carotid endarterectomy, thrombolytics, anticoagulant therapy, antiplatelet agents, neuroprotective agents, and treating associated risk factors such as hypertension and dyslipidemia have failed to reduce the burden of stroke. Current understanding of inflammation and ischemia has caused a paradigm shift in the perspective of stroke pathogenesis and outcome. It has also opened newer avenues in stroke management and prevention strategies, beyond the realms of antithrombotics. Though one needs to keep abreast with recommended protocols for stroke management, knowledge of the underlying patho-genetic process, aided by laboratory investigations and imaging, may usher in more therapeutic options. Well-designed clinical trials of novel therapeutic agents and strategies will be able to substantiate or refute their clinical usefulness, and confirm the possibility of being incorporated into evidence-based practice guidelines.

Several complex and overlapping pathways underlie the pathophysiology of cell death after ischemic stroke. While pharmaceutical agents can inhibit these pathways at various levels, resulting in effective neuroprotection in experimental models, no single agent intended for neuroprotection has been shown to improve outcome in clinical stroke trials. Refinements in patient selection, brain imaging, and methods of drug delivery, as well as the use of more clinically relevant animal stroke models and use of combination therapies that target the entire neurovascular unit, are warranted to make stroke neuroprotection an achievable goal. Ongoing trials assessing the efficacy of thrombolysis with neuroprotective agents and strategies aimed at extending the therapeutic window for reperfusion therapy promise to enhance the known benefits of reperfusion therapy. Most investigators agree that genomics and proteomics are the most promising recent developments impacting the future of stroke prevention, diagnosis, treatment, and outcome. Although many challenges lie ahead, an attitude of cautious optimism seems justified at this time.

ABSTRACT

Two important pathophysiological mechanisms involved during a stroke are oxidative stress and inflammation. Brain tissue is not well equipped with antioxidant defenses, so reactive oxygen species and other free radicals/oxidants, released by inflammatory cells, threaten the tissue viability in the vicinity of the ischemic core. In a stroke, cerebral blood vessels are the first to be exposed to the ischemic insult, and their reaction to injury sets the stage for the inflammatory response. Molecules released from injured or dying brain cells also contribute to the inflammatory response. Focal ischemia evokes a robust inflammatory response that begins within a few hours of onset and typifies the secondary or delayed response to ischemia. Hence there is a notion that taming post-ischemic inflammation may block secondary events that extend brain injury. However, as noted below, during the later stages in the injury process, inflammation promotes critical events necessary for tissue repair. Here in this chapter, we will discuss the molecular aspects of oxidative stress and inflammation in an ischemic stroke and potential therapeutic strategies that target neuroinflammation and the innate immune system. Currently, little is known about endogenous counter regulatory immune mechanisms. However, recent studies show that regulatory T cells are major cerebral-protective immunomodulators after stroke, suggesting that targeting the endogenous adaptive immune response may offer novel promising neuroprotectant therapies. New research has shown that brain ischemia and trauma elicit strong inflammatory reactions driven by both external and brain cells. The recognition of inflammation as a fundamental

response to brain ischemia provides novel opportunities for new anti-inflammatory therapies. Hypertension, cardiovascular disease, arterial fibrillation, diabetes mellitus, smoking, and alcohol abuse are all risk factors for a stroke. Clinical observations suggest that inflammation is also a direct risk factor for a stroke. Recent studies have shown that plasma levels of inflammatory cytokines or soluble adhesion molecules are high in non-stroke patients, and anti-inflammatory therapy is effective at reducing the stroke incidence in not only animal models, but in humans as well. Statins have been shown to decrease the stroke incidence via anti-inflammatory effects that are both dependent and independent of their cholesterol-lowering effects. These reports suggest that inflammation might directly affect the onset of a stroke. Here in this chapter, we present the latest findings about the cellular and humoral aspects of immune and inflammatory reactions in the brain. They may have an impact on the treatment of neuro-injuries and ancillary brain diseases, and increase the understanding of the roles infections and immune reactions play in the brain milieu.

INTRODUCTION

Strokes are an important issue in public health due to their high rates of morbidity and mortality, and disability. A stroke is one of the most common causes of death and disability worldwide (Lyod Johnes D 2009). However, current therapeutic strategies for strokes have been largely unsuccessful. One possible explanation is that research and pharmacological management have focused on very early events in brain ischemia. New research has shown that brain ischemia and trauma elicit strong inflammatory reactions driven by both external and brain cells. The recognition of inflammation as a fundamental response to brain ischemia provides novel opportunities for new anti-inflammatory therapies. Hypertension, cardiovascular disease, arterial fibrillation, diabetes mellitus, smoking, and alcohol abuse are all risk factors for a stroke. Clinical observations suggest that inflammation is also a direct risk factor for a stroke. Stroke patients have high levels of inflammatory cytokines in plasma, and immune cells, such as macrophages and T-lymphocytes, are noted within stroke lesions. These inflammatory events are considered as a result of a stroke. However, recent studies show that plasma levels of inflammatory cytokines or soluble adhesion molecules are high in non-stroke patients, and anti-inflammatory therapy is effective at reducing stroke incidence in not only animal models, but in humans as well. Statins have been shown to decrease the stroke incidence via anti-inflammatory effects that are both dependent and independent of their cholesterol-lowering effects. These reports suggest that inflammation might directly affect the onset of a stroke. Microglial cells and blood-derived monocytes/macrophages play important roles in inflammation in both onset and aggravation of stroke lesions. Two important pathophysiological mechanisms involved during an ischemic stroke are oxidative stress and inflammation. Brain tissue is not well equipped with antioxidant defenses, so reactive oxygen species and other free radicals/oxidants, released by inflammatory cells, threaten the tissue viability in the vicinity of the ischemic core. This chapter will discuss the molecular aspects of oxidative stress and inflammation in ischemic strokes and potential therapeutic strategies that target neuroinflammation and the innate immune system. Currently, little is known about endogenous counterregulatory immune mechanisms. However, recent studies show that regulatory T cells are major cerebroprotective immunomodulators after a

stroke suggesting that targeting the endogenous adaptive immune response may offer novel promising neuroprotectant therapies.

Here in this chapter, we present the latest findings about the cellular and humoral aspects of immune and inflammatory reactions in the brain. They may have an impact on the treatment of neuro-injuries and ancillary brain diseases, and increase the understanding of the roles infections and immune reactions play in the brain milieu. Although different mechanisms are involved in the occurrence and development of a stroke, inflammatory response is greatly involved in its sequence (Barone FC 2001). Inflammation is intricately related to the onset of a stroke and to subsequent stroke-related tissue damage. Focal ischemia evokes a robust inflammatory response that begins within a few hours of onset and typifies the secondary or delayed response to ischemia (Figure 3.1). Inflammation within the arterial wall plays a vital role in promoting atherosclerosis (Chomorro A 2004, Elkind MS 2002). Arterial thrombosis (usually associated with ulcerated plaques) is triggered by multiple processes involving endothelial activation, and proinflammatory and prothrombotic interactions between the vessel walls and circulating blood elements. An elevated stroke risk has been linked to high levels of serologic markers of inflammation such as C-reactive protein (Ridker PM 2000), ESR, interleukin-6, TNF-alpha, and soluble intercellular adhesion molecule (sICAM) (Tanne D 2000). These events are promoted in part by the binding of cell adhesion molecules from the selectin and immunoglobulin gene families expressed on endothelial cells to the glycoprotein receptors expressed on the neutrophil surface. As evidence, reduced ischemic infarction is observed in ICAM-1 knockout mice and infarction volumes are increased in mice that overexpress P-selectin (Connolly ES 1996 and 1997). The proinflammatory molecule P-selectin is expressed on vascular endothelial within 90 min after cerebral ischemia, ICAM-1 by 4 h, and E-selectin by 24 h (del Zoppo G 2000).

Figure 3.1. Inflammation Putative cascade of damaging events in focal cerebral ischemia. Very early after the onset of the focal perfusion deficit, excitotoxic mechanisms can damage neurons and glia lethally. In addition, excitotoxicity triggers a number of events that can further contribute to the demise of the tissue. Such events include peri-infarct depolarizations and the more-delayed mechanisms of inflammation and programmed cell death. The x-axis reflects the evolution of the cascade over time, while the y-axis aims to illustrate the impact of each element of the cascade on final outcome (courtesy of Dirnagl et al. 1999).

Inhibiting both selectin adhesion molecules and activation of complement reduces brain injury and suppresses neutrophil and platelet accumulation after focal ischemia in mice (Huang J 1999). In humans, neutrophil and complement activation significantly worsened outcomes in a clinical trial using humanized mouse antibodies directed against ICAM Enlimomab (Enlimomab 2000). Hence, the complexities of interactions between multiple pathways will have to be carefully considered for optimal translation to the clinic. Ischemic stroke-related brain injury itself triggers inflammatory cascades within the parenchyma that further amplify tissue damage (del Zoppo G 2000). As reactive microglia, macrophages, and leukocytes are recruited into ischemic brain, inflammatory mediators are generated by these cells as well as by neurons and astrocytes. Inducible nitric oxide synthase (iNOS), cyclooxygenase-2 (COX-2), interleukin-1 (IL-1), and monocyte chemoattractant protein-1 (MCP-1) are key inflammatory mediators, as evidenced by attenuated ischemic injury in mutant mice with targeted disruption of these genes (Barone FC 1999, Huggs PM 2002, Ledecolla C 2001, Boutin H 2001).

Initially after occlusion, there is a transient upregulation of immediate early genes encoding transcription factors (e.g., c-fos, c-Jun) that occurs within minutes. This is followed by a second wave of heat shock genes (e.g., HSP70, HSP72) that increases within 1–2 h and then decreases by 1–2 days. Approximately 12–24 h after a stroke, a third wave comprised of chemokines and cytokines is expressed (e.g., IL-1, IL-6, IL-8, TNF-alpha, MCP-1, etc.). Whether or not these three waves are causally related is not known. Nevertheless, therapies that seek to target these pathways need to be carefully timed to match the complex temporal evolution of tissue injury. Inflammatory Cascades stimulate both detrimental and potentially beneficial pathways after ischemia. For example, administering TNF-alpha neutralizing antibodies reduces brain injury after focal ischemia in rats (Nawashiro H 1997), whereas ischemic injury increases in TNF receptor knockout mice (Bruce AJ 1996). In part, these contrasting results may reflect signal transduction cascades activated by TNF-R1 and TNF-R2, with TNF-R1 augmenting cell death and TNF-R2 mediating neuroprotection (Fountaine V 2002). Similarly, the peptide vascular endothelial growth factor (VEGF) exacerbates edema in the acute phase of cerebral ischemia, but promotes vascular remodeling during stroke recovery (Zhang ZG 2000). Ultimately, the net effect of these mediators depends upon the stage of tissue injury or the predominance of a single signaling cascade among multiple divergent pathways.

In the early stage of cerebral ischemia, circulating leukocytes including neutrophils, macrophages, and lymphocytes migrate and adhere to the injured endothelial cells and infiltrate into the ischemic brain region *via* a dysfunctional blood–brain barrier (Lakhan SE 2009). The inflammatory response is also characterized by endogenous microglia activation following focal cerebral ischemia (Hellenbeck JM 1996, Morioka T 1993, Wang Q 2007). The infiltration of blood derived leukocytes and macrophages liberate toxic and inflammatory mediators involved in a “no reflow phenomenon” and amplify the ischemic brain injury (Yilmaz G 2010).

Post-ischemic reflow, either due to collateral circulation establishment or therapeutic recanalization, leads to the generation of reactive oxygen species (ROS), which then stimulates ischemic cells, including neurons and astrocytes to secrete inflammatory cytokines, chemokines and adhesion molecules (Ceulemans AG 2010). Once the inflammatory cascade is activated, inflammatory cells can release a variety of cytotoxic agents, including more cytokines, matrix metalloproteinases (MMPs), nitric oxide (NO) and induce more cell

damage as well as disruption of the blood–brain barrier (BBB) and extracellular matrix (Denton GH 2003, Emsley HC 2002). Blocking various aspects of the inflammatory cascade was shown to attenuate ischemic brain injury from an experimental stroke (Han HS 2003) although this has yet to be demonstrated clinically (Becker K 2001). Exploration of ischemia-induced inflammatory related biomarkers therefore is important and necessary to understand the mechanism of ischemia-induced inflammatory brain injury.

During cerebral ischemia, inflammatory cytokines interleukin (IL)-1 β , IL-6 and tumor necrosis factor (TNF), are extremely up-regulated (up to 40- to 60-fold) at least in the brain within the first 24 h of an experimental stroke model (Clausen 2005 and 2008, Hill JK 1999, Lambertsen 2005). These three cytokines are able to affect the volume of the ischemic induced tissue damage in a rodent experimental stroke model (Yang GY 1999). These cytokines also increase in cerebro-spinal fluid (CSF) and circulating blood after an ischemic stroke in humans (Allan SM 2005, McCoy MK 2008 and Whiteley W 2009). Although IL-1 β , IL-6, and TNF α are among the most investigated cytokines in CSF and blood in human stroke patients, their availability and mechanism of action in the human brain in the early phase after an experimental stroke remain unknown (Ginsberg MD 2008). Besides these three cytokines, other factors such as IL-8, IL-10, CD40L, IFN γ , IL-1 α , IL-17, and TGF β also participate in the inflammatory response after an ischemic stroke (Pang L 2001 and Smith CJ 2004). Understanding the cellular production of cytokines in normal brain, and the time profile and the cellular sources of these cytokines, and the possibilities of their transport in the ischemic territory in the early phase after the onset of a stroke is crucial to unveiling the mechanisms by which these cytokines potentially affect brain damage after an ischemic stroke. A panel of cytokines has been shown to vary their presence in the peripheral blood after cerebral ischemia, which is associated with changes of their levels in the brain tissue or the cerebral spinal fluid (CSF). However, the principal shortcoming including a high individual variance of circulating cytokine levels limited the establishment of clinical criteria for control groups. Using a modified method (mosaic ELISA kits), Zeng et al. has detected a cluster of cytokines in each sample at the same time. This novel method required less volume of a blood sample and significantly decreased biological error compared to other studies using single ELISA assay.

To establish a relevant control group is critical in clinical stroke studies. In most cases, studies are limited to the choice of healthy volunteer as a control group. Chronic disease such as diabetes, hypertension, hyperlipidemia also influence a chronic inflammatory response and result in the release of numerous circulating cytokines (Spraner J 2003 Greenberg AS 2006 and Wisse BE 2004). Stroke patients usually suffer a significantly higher frequency of cardiovascular risk factors compared to the healthy controls. Hence, the difference in circulating cytokine levels between the stroke group and the control group could not exclude the influence of cardiovascular risk factors. To eliminate this factor, Zeng et al. chose age, sex, cardiovascular risk factors matched normal controls to eliminate the influence of cardiovascular risk factors. As a result, they found that among the most studied panel of pro-inflammatory cytokines, IL-6 was the only one that was not up-regulated in plasma after cerebral ischemia but also correlated with the severity of neurological impairment.

Numerous studies have revealed a close relationship between pro-inflammatory cytokine release and post-stroke, inflammatory injury (Dnes A 2010, Lambertsen KL 2005 and Spalata G 2006). Although many studies focus on the clinical significance of individual cytokine, each source of circulating cytokines is unclear. A study on the source of cytokines in

peripheral blood is useful to better understand the function of cytokine both in peripheral and brain inflammation. There are three major hypotheses:

- (1) Cytokines are released into circulating blood by inflammatory cells in ischemic brain tissue *via* an impaired blood–brain barrier;
- (2) Cytokines are secreted and released by activating leukocytes such as neutrophils, lymphocytes and monocytes;
- (3) Cytokines are released by peripheral immune organs

However, some researchers (Planas Am 2006, Wang Q 2007, Tutolomonodo A 2008) did not find a positive relationship between plasma cytokine protein level and their RNA level in leukocyte. Therefore, the source of circulating cytokines needs to be further studied in the future. The interaction of cytokines is another important issue which is largely unknown. It is interesting that Zeng et al. adopted Bayesian network (BN) learning procedure in an attempt to understand the interactions (inter-influencing network) among the 8 cytokines in protein and mRNA level after an ischemic stroke. The BN method is used widely in many fields, including protein–protein interactions (Bradford JR 2006, Hack CE 2010), gene function analysis (Zhao B 2011), and brain functional connectivity using MRI (Burge J 2009). Zeng et al. used this method to explore the interaction among circulating pro-inflammatory cytokines in patients with acute ischemic stroke. Although the data need to be further confirmed by others, the original result revealed a suspected complex circulating pro-inflammatory cytokine network model with positive and negative feedback. Pro-inflammatory cytokine up-regulation in plasma and compensatory immunity, depression in leukocyte involve in peripheral inflammatory response to ischemic brain injury. IL-6 activation is a potential therapeutic target for stroke therapy to attenuate secondary inflammatory injury. The detailed cytokine network during ischemia development calls for further investigation with animal experiments *in vivo* and *in vitro*.

The most common cause of a stroke is the sudden occlusion of a blood vessel by a thrombus or embolism, resulting in an almost immediate loss of oxygen and glucose to the cerebral tissue. Although different mechanisms are involved in the pathogenesis of a stroke, increasing evidence shows that ischemic injury and inflammation account for its pathogenic progression (Muir KW 2007). Cerebral ischemia triggers the pathological pathways of the ischemic cascade and ultimately causes irreversible neuronal injury in the ischemic core within minutes of the onset (Dirnagl U 1999). However, a much larger volume of brain tissue surrounding this ischemic core, known as the penumbra, can be salvaged if cerebral blood flow is promptly restored. Thus, the original definition of the ischemic penumbra referred to areas of the brain that were damaged but not yet dead, offering the promise that if proper therapies could be found, one could rescue brain tissue after a stroke and reduce post-stroke disability. Despite advances in the understanding of the pathophysiology of cerebral ischemia, therapeutic options for acute ischemic stroke remain very limited (Donnan GA 2008). Only one drug is approved for clinical use for the thrombolytic treatment of acute ischemic stroke in the US and that is intravenous recombinant tissue plasminogen activator (rt-PA). When delivered within three hours after symptom onset, rt-PA reduces neurological deficits and improves the functional outcome of stroke patients. However, this improvement in recovery is achieved at the expense of an increased incidence in symptomatic intracranial hemorrhage, which occurs in ~6% of patients. Furthermore, since the large majority of patients with acute

ischemic stroke do not go to the hospital within three hours of stroke onset most do not receive rt-PA treatment (Furlan AJ 2003). Consequently, the successful treatment of acute ischemic stroke remains one of the major challenges in clinical medicine. This chapter will provide a brief overview of the current understanding of the inflammatory mechanisms involved in an acute ischemic stroke and the neuroprotective agents that can curtail neuroinflammation and potentially show utility in the treatment of a stroke. Neuroprotective treatments or therapies block the cellular, biochemical, and metabolic elaboration of injury during exposure to ischemia. Of the more than 100 neuroprotective agents that reached randomized clinical trials in focal ischemic stroke, none has proven unequivocally efficacious, despite success seen in preceding animal studies (O'Collins VE 2006). However, the field trials of the past have greatly increased our understanding of the fundamental biology of ischemic brain injury and have laid a strong foundation for future advance. New anti-inflammatory targets continue to be identified, which is an important area of translational medicine in acute stroke. Overall, the prospects for safe neuroprotective therapies to improve stroke outcomes remain promising (De la Ossa NP 2007).

IMMUNE ACTIVATION AND SYSTEMIC INFLAMMATION BEFORE A STROKE

The immune system plays a role in the development of atheromatous plaque and in plaque rupture (Koenig W 2007). The production of atheromatous plaque involves local inflammation within the wall of blood vessels (Croce K 2007, Hansson GK 2006). The cells in the plaque include macrophages, CD4 and CD8 T cells (Xu QB 1990, Jhonsson L 1990). One target of the immune attack in atherosclerosis is oxidized low density lipoprotein (oxLDL), which is highly immunogenic (Kobayashi K 2005). Some of the T cells in plaque are likely to be specific for oxLDL, as tolerance to oxLDL reduces the severity of atheroma through a mechanism involving regulatory T cells (Treg cells) (Mor A 2007, Van Puijvelde Gh 2006). The entry of leukocytes into tissue is mediated by endothelial expression of adhesion molecules, such as vascular cell adhesion molecule-1 (VCAM-1), intercellular adhesion molecule-1 (ICAM-1) and E-selectin and L-selectin (Moller F 2005, Galkina E 2006). Chemokines are members of a large superfamily of small molecules that have a role in the movement of leukocytes through tissues. This occurs through interaction with chemokine receptors on cells (Colobran R 2007). Chemokines play a role in the entry of lymphocytes into atheromatous plaque. For example, CXCR6 is required for the entry of CXCR6 cells into atheromatous plaque (Galkina E 2007) and CXCL10 attracts effector T cells into plaque (Heller EA 2006). Another factor that regulates atherogenesis is an expression of CD40, which is a glycoprotein expressed on many cells including endothelial cells. Ligation of CD40 on endothelium results in endothelial activation. CD40 interacts with CD40 ligand (CD40L), which is expressed on CD41 T cells. CD40 is important in the entry of T cells into plaque and also in plaque activation (Mach F 1997) T cells that have entered an atheromatous plaque may release cytokines that lead to plaque rupture (Tedgui A 2006).

Systemic inflammation, measured as high levels of C-reactive protein (CRP) (Tanne D 2006) or fibrinogen (Zhu YC 2006), is a risk factor for a stroke (Elkind MS 2006). There is debate as to whether, in individual patients, there is a causal relationship between elevated

levels of these proteins and stroke incidence. A recent study suggests that patients with echolucent plaques, that are likely to rupture, have higher levels of systemic inflammation than patients with plaques that are less likely to rupture (Withnoto AT 2006). Thus, inflammatory processes may predispose to stroke. Furthermore, in experimental animals, systemic inflammation induced by injection of lipopolysaccharide (LPS) causes exacerbation of damage through pathways involving interleukin-1 (IL-1) (McColl BW 2007). The brain is considered to be a site of relative immunological privilege, because of the relative lack of rejection of foreign tissue that has been transplanted into the brain (Simpson E 2006). Microglia, which are the resident antigen-presenting cells in the brain, are thought to provide constant surveillance of tissue injury (Nimerjhan A 2005) and become activated when injury occurs. However, for an adaptive immune response to occur, antigen-presenting cells must travel to draining lymph nodes. Microglia are thought to have little or no ability to travel to draining lymph nodes, which has been put forward as one reason for the relative immune privilege of the brain (Melchior B 2006). Nevertheless, there is immune surveillance of the brain and there are local immune responses to brain injury (Lucas SM 2006). As well as parenchymal microglia, the brain also has perivascular macrophages (Kim WK 2006) that are hematogenous in origin. Furthermore, in strokes, and in other pathological states, breakdown of the blood-brain barrier (Wang PY 1993) means that the injured tissue becomes relatively more exposed to immune processes with entry of blood-borne inflammatory cells. Macrophages of the brain are able to travel to draining lymph nodes to initiate adaptive immune responses (Fabreik BO 2005).

POST-ISCHEMIC INFLAMMATION

Although for many years the CNS was considered an immune-privileged organ, it is now well accepted that the immune and the nervous system are engaged in bidirectional crosstalk. Moreover, mounting data suggest that in the brain, as in peripheral organs, inflammatory cells participate in tissue remodeling after injury. Microglial cells are the resident macrophages of the brain and play a critical role as resident immunocompetent and phagocytic cells in the CNS. Ekdahl and colleagues (Ekdahl CT 2009) reported an increased number of activated microglial cells up to 16 weeks after two hours MCAO in rats. After activation by ischemia, microglia can transform into phagocytes and they can release a variety of substances, many of which are cytotoxic and/or cytoprotective. Microglia may exert neuroprotection by producing neurotrophic molecules such as brain-derived neurotrophic factor (BDNF), insulin-like growth factor I (IGF-I), and several other growth factors. There is substantial evidence that activated microglial cells in response to ischemia have the potential of releasing several pro-inflammatory cytokines such as TNF- α , IL-1 β , and IL-6, as well as other potential cytotoxic molecules including NO, ROS, and prostanoids (Lucas SM 2006). Astrocytes, like microglia, are capable of secreting inflammatory factors such as cytokines, chemokines, and NO (Swanson RA 2004). Cytokines upregulate the expression of cell adhesion molecules (CAMs). Within four to six hours after ischemia onset, circulating leukocytes adhere to the vessel walls and migrate into the brain with subsequent release of additional pro-inflammatory mediators and secondary injury in the penumbra. Neutrophils are the earliest

leukocyte subtype to show substantial upregulation in gene expression studies and to infiltrate areas of brain ischemia (see figure 3.2).

Recently, Shichita et al. (Shichita T 2009) demonstrated an infiltration of γ δT cells 3 days after the onset of ischemia in a mouse model, along with a production of IL-17 which amplifies the inflammatory cascade. IL-23 from infiltrating macrophages appears to produce IL-23 which attracts the infiltrating γ δT cells. Blocking a specific γ δT cell receptor with an antibody effectively reduced three day infarct volumes, even when treatment was initiated at 24 hours after onset of cerebral ischemia. Targeting these γ δT cells may offer a clinical opportunity with a longer therapeutic window to prevent the secondary inflammatory expansion of cerebral damage after a stroke. The described post-ischemic neuroinflammatory changes lead to dysfunction of the brain tissue. Therefore, therapeutic targeting of the neuroinflammatory pathways in acute ischemic strokes has become an important area of research in translational medicine.

Figure 3.2. Postischemic inflammatory responses. Excitotoxicity and oxidative stress caused by the initial ischemic event activate microglia and astrocytes, which react by secreting cytokines, chemokines and matrix metalloproteases (MMP). These inflammatory mediators lead to an upregulation of cell adhesion molecules on endothelial cells, allowing blood derived inflammatory cells, mainly neutrophils, to infiltrate the ischemic brain area. Neutrophils themselves also secrete cytokines which cause a further activation of glial cells. These processes all result in neuronal cell death and enhance the damage to the ischemic brain.

Cytokines and Brain Inflammation

Cytokines are a group of small glycoproteins that are produced in response to an antigen and were originally described as mediators for regulating the innate and adaptive immune systems. Cytokines are thus upregulated in the brain in a variety of diseases, including strokes. In the brain, cytokines are expressed not only in the cells of the immune system, but are also produced by resident brain cells, including neurons and glia (Barone FC 1999). In addition, it has been shown that peripherally derived cytokines are involved in brain inflammation. Thus, peripherally derived mononuclear phagocytes, T lymphocytes, NK cells and polymorphonuclear leukocytes produce and secrete cytokines and might contribute to inflammation of the CNS (Ferrarese C 1999).

The most studied cytokines related to inflammation in an acute ischemic stroke are tumor necrosis factor- α (TNF- α), the interleukins (IL), IL-1 β , IL-6, IL-20, IL-10 and transforming growth factor (TGF)- β . While IL-1 β and TNF- α , appear to exacerbate cerebral injury, TGF- β and IL-10 may be neuroprotective (Zhu Y 2002, Spera PA 1998). Increased production of proinflammatory cytokines and lower levels of the anti-inflammatory IL-10 are related to larger infarctions and poorer clinical outcome. Elevated IL-1 β mRNA expression occurs within the first 15-30 min after permanent MCAO and elevated IL-1 β protein expression occurs a few hours later and remains elevated for up to 4 days (Caso JR 2007). There are studies that correlate an increase in the levels of IL-1 β after ischemia with worsening of the infarct severity. For example, Yamasaki et al. (Yamasaki Y 1995) demonstrated that intraventricular injection of recombinant IL-1 β after MCAO increases the formation of brain edema, the volume of the size and the influx of neutrophils. In addition, IL-1 β deficient mice presented smaller infarcts in comparison with wild-type mice (Boutin H 2001). High circulating IL-1 β elevates circulating IL-6, other well-known cytokine that is upregulated following cerebral ischemia (Clark WM 1999). Moreover, the serum level of IL-6 correlates with brain infarct volume (Acalovschi D 2003) and is a powerful predictor of early neurological deterioration (Vila N 2001). On the other hand, Clark et al. (Clark WM 2001) demonstrated that infarct size and neurological function were not different in animals deficient in IL-6 after transient CNS ischemia. This suggests that IL-6 does not have a direct influence on acute ischemic injury. IL-20 is induced when IL-1 β modulates p38 MAPK and the NF- κ B pathway. IL-20 in turn induces the production of IL-6. Inhibition of IL-20 by a specific mAb significantly ameliorated the brain ischemic infarction in rats following MCAO (Chen WY 2009). Several approaches are under investigation for managing IL-1 in a stroke (Table 1). IL-1 acts via membrane receptors (IL-1R), which can be blocked by a receptor antagonist (IL-1RA). In a randomized trial for an acute stroke, IL-1RA readily crossed the blood-brain barrier, was safe to use, and seemed to afford some benefit, particularly for patients with cortical infarcts (Gueorguieva I 2008). IL-10 is an anti-inflammatory cytokine that acts by inhibiting IL-1 and TNF- α , and by suppressing cytokine receptor expression and receptor activation as well. As a consequence, IL-10 could provide neuroprotection in acute ischemic strokes. Both central and systemic administration of IL-10 to rats subjected to MCAO significantly reduced infarct size 30 min to three hours post MCAO (30). In acute ischemic strokes, elevated concentrations of IL-10 in CSF have been found (Tarkowski E 1997). Moreover, patients with low plasma levels (<6 pg/ml) of IL-10 during the first hours after a stroke were three times more likely to have worsening neurological symptoms within

48 hours following the stroke (Vila N 2001). IL-10 also seems to mediate the reduction in infarct size by regulatory T cells.

Table 1. Clinical studies of agents targeting inflammatory pathways in acute ischemic strokes

S. No	Neuro-protective agent	Mode of action	Reference
1	Enlimomab	Anti-ICAM-1 monoclonal antibody	Enlimomab 2001
2	Cerovive (NXY-059)	Nitrone-based free radical trapping agent	Lyden PD et al. 2007 Shuyaib A et. al. 2007
3	Recombinant human IL-1RA	Interleukin-1 receptor antagonist	Emsley HC et al. 2005
4	UK-279, 276	Neutrophil inhibitory factor	Krams M et al. 2003
5	Tirilazad	Lipid peroxidation inhibitor	Bath PM et al. 2001
6	Ginsenoside	Ca ²⁺ channel antagonist	Liu X et al. 2009
7	Edaravone MCI-186	Free radical scavenger	Edaravone Study Group 2003
8	Acetaminophen (Paracetamol)	Anti-pyretic effect	Van Breda EJ et al. 2005
9	Minocycline	Anti-inflammatory	Lampl Y et. al. 2007
10	ONO-2506 (Arundic Acid)	Astrocyte modulator	Pettigrew LC et al. 2006

Chemokines and Brain Inflammation

Chemokines, for example, monocyte chemoattractant protein 1, are a class of cytokines that guide the migration of blood borne inflammatory cells, such as neutrophils and macrophages, towards the source of the chemokine. Consequently, they play important roles in cellular communication and inflammatory cell recruitment. Expression of chemokines such as MCP-1, macrophage inflammatory protein-1 α (MIP-1 α), and fractalkine following focal ischemia is thought to have a deleterious effect by increasing leukocyte infiltration (Kim JS 1995). The level of a variety of chemokines has been found to increase in animal models of ischemia and their inhibition or deficiency has been associated with reduced injury (Soriano S 2002, Huges PM 2002). Mice without the chemokine receptor CCR2 are protected against ischemia-reperfusion injury (Dimitrijevic OB 2007).

Cellular Adhesion Molecules

There is increasing evidence that cellular adhesion molecules (CAMs) play an important role in the pathophysiology of an acute ischemic stroke. CAMs are upregulated in the first days after a stroke by various cytokines and are responsible for the adhesion and migration of the leukocytes. Leukocytes roll on the endothelial surface and then adhere to the endothelial cells. The interaction between leukocytes and the vascular endothelium is mediated by three main groups of CAMs: the selectins, the immunoglobulin gene superfamily, and the integrins. Selectins, especially E- and P-selectins are upregulated and mediate leukocyte rolling and

recruitment during the early stages of ischemia (Zhang, R 1998) Among the immunoglobulin family member, intercellular adhesion molecule-1 (ICAM-1) and vascular cell adhesion molecule-1 have been the most extensively investigated in cerebral ischemia. Within hours after the onset of stroke, ICAM-1 expression increases upon stimulation by cytokines (Lindsberg PJ 1996). Patients with acute ischemic strokes had higher soluble intracellular adhesion molecule-1 (sICAM-1) levels compared to patients without cardiovascular disease. Moreover, sICAM-1 levels were significantly higher in patients who died compared to those who survived (Rallidis LS, 2009). High sICAM-1 levels on admission are associated with early death in ischemic middle-aged stroke patients, suggesting a pathogenic role of inflammation in the evolution of ischemic strokes.

A number of animal studies have shown that after transient and permanent focal ischemia the upregulation of CAMs, especially ICAM-1, P- and E-selectin, preceded the invasion of neutrophils into the brain. There is ample evidence from animal models of MCAO that expression of CAMs is associated with cerebral infarct size. Thus, genetic ablation of CAMs resulted in reduced infarct size, which could be mimicked by treatment with anti-CAM antibodies (Zhang RL 1994, Gossev AV 1998). Inhibition of leukocyte activation and infiltration into the ischemic cerebral tissue has, therefore, been an important area of neuroprotection research. Thus far, anti-CAM treatment has not been successful in patients with acute ischemic strokes. However, further translational research into the therapeutic targeting of CAM is ongoing. The spatiotemporal profile of CAMs is still largely unresolved, even though they are crucial for efficient anti-inflammatory therapies. More knowledge of the spatiotemporal profile of CAMs may lead the way to successful application and monitoring of promising anti-inflammatory treatment strategies after a stroke.

Matrix Metalloproteinases

MMPs are a family of proteolytic enzymes that are responsible for remodeling the extracellular matrix and that can degrade all its constituents. Expression of MMPs in the adult brain is very low to undetectable, but many MMPs are upregulated in the brain in response to injury (Montaner J 2001).

Neurons, astrocytes, microglia, and endothelial cells have all been shown to express MMPs after injury. A stroke is associated with a biphasic disruption of the blood brain barrier (BBB) leading to vasogenic edema and hemorrhage and experimental studies have shown that that BBB breakdown and hemorrhage results from the expression and activation of MMPs (Asaie M 2001). MMP-2 and MMP-9 have been implicated in cerebral ischemia. Elevated MMP-9 levels were found in brain tissue and in serum from patients with acute ischemic strokes and in animal models of strokes beginning at 12 h after permanent MCAO (Park KP 2009).

MMP-9 is normally absent and this is the major MMP associated with neuroinflammation. Early (day 1) MMP-9 inhibition reduced infarction of day 14. However, the benefit was lost when the treatment was delayed until day 3 and the stroke pathology was exacerbated when the administration was delayed until day 7. These studies all suggest that MMP inhibition could have a beneficial effect on the outcome of a stroke, but the effect will depend on the timing of treatment in relation to the stage of brain injury (Zhao BQ 2006).

PROINFLAMMATORY CYTOKINES IN STROKES

A stroke is the third leading cause of death and a major cause of disability in industrialized countries. An ischemic stroke is the most common type of stroke, occurring in approximately 80% of all strokes. A less common type of stroke is a hemorrhagic stroke, which occurs due to a subarachnoid hemorrhage and/or an intracerebral hemorrhage. Hypertension, cardiovascular disease, arterial fibrillation, diabetes mellitus, obesity, smoking, and alcohol abuse are risk factors for a stroke (Goldstein LB 2011), even if there are slight differences in the influence of these factors between ischemic stroke and hemorrhagic stroke. However, some stroke patients do not have any of these risk factors, suggesting that other risk factors exist. For many years, clinical observations showed that plasma levels of inflammatory cytokines were increased after stroke onset, and immune cells, especially monocytes/macrophages and T-lymphocytes, existed in stroke lesions and related to exaggerate brain damage. In the clinical setting, elevated plasma levels of inflammatory cytokines, C-reactive protein (CRP), and chemokines are associated with future cardiovascular risk (Blake GJ 2002). Plasma levels of soluble intercellular adhesion molecule-1 (sICAM-1) and sE-selectin were observed to be increased both in large intracranial artery disease and small-artery disease (Fassbender K 1999), and plasma levels of ICAM-1 and monocyte chemoattractant protein-1 (MCP-1) were noted to be high in patients with ischemic stroke and myocardial infarction (Sánchez-Moreno C 2004, Arakelyan A 2005). Epidemiological studies have shown that elevated leukocyte count was associated with the risk for first-time myocardial infarction and ischemic stroke (Prentice RL 1982, Fawa M 1987, Gillum RF 1994) and the risk of recurrent myocardial infarction and ischemic stroke in a high-risk population (Grau AJ 2004). These observations indicate that inflammatory events occur in stroke patients and increase the risk of stroke recurrence. Recently, both clinical and animal studies revealed that these inflammatory events occurred prior to stroke onset. Plasma levels of soluble vascular cell adhesion molecule-1 (sVCAM-1), sICAM-1, sE-selectin, and MCP-1 were elevated in patients with essential hypertension in the absence of other diseases (Blann AD 1994, Madej A 2005, Desouza CA 1997). Anti-inflammatory strategies were shown to suppress the incidence of a stroke in both human and animal models. These reports suggest that inflammation might be a risk factor for a stroke. Atherosclerosis is one of the major risk factors for a stroke, and monocytes/macrophages affect the brain indirectly by inducing unstable plaques and plaque rupture in atherosclerotic lesions (Newby AC 2008). It is well recognized that atherosclerosis is an inflammatory disease and macrophages play important roles in the initiation and the progression of atherosclerotic lesion. Accumulation of monocytes/macrophages in the vascular wall occurs early during atherosclerosis (Ross R 1999). In addition to phagocytosis of oxidized low-density lipoproteins, macrophages secrete interleukin- 1β (IL- 1β), tumor necrosis factor- α (TNF- α), and transforming growth factor- β 1 (TGF- β 1). These inflammatory cytokines and growth factors induce endothelial dysfunction, smooth muscle cell migration and proliferation, and extracellular matrix production as fibrous plaques. During later disease stages, activated macrophages secrete several classes of neutral extracellular proteases, including serine proteases, cathepsins, and matrix metalloproteinases (MMPs) (Dollery AM 2006). Blood monocytes have already expressed low levels of a few MMPs (Bar-Or A 2003); however, contact with matrix leads to rapid upregulation of a broad spectrum of MMPs. Cell biology experiments identify mechanisms by which excessive MMP

production can cause plaque rupture, either directly by destruction of extracellular matrix or indirectly through actions that promote death of macrophages (Johnson JL 2008) and vascular smooth muscle cells (Newbay AC 2006). Rupture of unstable plaques may lead to thrombotic stroke onset. Inflammatory cytokines, such as IL-1 β , IL-6, and TNF- α , are secreted by activated microglial cells and macrophages in stroke lesions and induce the expression of chemokines, which recruit more circulating monocytes/macrophages into lesions and lead to further brain damage. However, the role of each cytokine in a stroke is complicated.

Figure 3.3. Inflammation: Monocytes/macrophages modulate adipose tissue and kidney functions and accelerate the onset of a stroke. Monocytes/macrophage infiltration into adipose tissue stimulates secretion of leptin and inflammatory cytokines and suppresses secretion of adiponectin, which induce systemic inflammation, endothelial cell dysfunction, and monocytes/macrophage activation. Monocytes/macrophages infiltration into kidney modulates renin-angiotensin system and increase blood pressure, which also induces endothelial cell dysfunction and monocytes/macrophages activation. Endothelial cells express MCP-1 and adhesion molecules, which induce monocytes chemotaxis, adhesion, and migration into subendothelial lesions. Microglial cells and infiltrated monocytes/macrophages in brain induce cerebrovascular damages and cause stroke onset.

Interleukin-1 β

Recently, IL-1 β has been considered a therapeutic target for a stroke. Chronic increases in IL-1 β expression in the brain led to leukocyte infiltration and increased MCP-1 and ICAM-1 expressions in a mouse model, which is a phenotype also seen in stroke lesions. In addition, a number of studies have demonstrated that inhibiting the release or action of IL-1 markedly

reduced ischemic cerebral damage in animal models. IL-1 α and IL-1 β double knockout mice exhibited dramatically reduced ischemic infarct volume compared with wild-type mice (Boutin H 2001). In a meta-analysis of animal model studies, IL-1 receptor antagonist (IL-1Ra), which represents the most advanced approach to modify IL-1 actions, reduced infarct volume in models of focal cerebral ischemia (Banwell V 2009). In humans, a phase II clinical trial of intravenous IL-1Ra compared with the placebo in patients with acute strokes is currently underway (Emsley HCA 2005). Further, IL-1Ra gene polymorphism represents a risk factor for an ischemic stroke (Olsson S 2012). These reports suggest that inhibition of IL-1 β signals can prevent the onset of a stroke.

Interleukin-6

A prospective cohort study and systemic review revealed that plasma levels of IL-6 were associated with poor outcome after both ischemic and hemorrhagic strokes (Whiteley C 2009); however, it was not clear whether IL-6 increased before or after stroke onset. Animal models showed less association between IL-6 and strokes. IL-6 could not induce adhesion molecules and MCP-1 mRNA expressions in cerebrovascular endothelial cells derived from SHRSP. Mice deficient in IL-6 showed similar stroke lesion volume and neurological function as control mice in an acute ischemic injury model (Clark WM 2000). Furthermore, IL-6 mediates anti-inflammatory effects in addition to its proinflammatory role (Scheller A 2011). Therefore, its manipulation can have either detrimental or beneficial effects. Further studies are required to clarify the role of IL-6 in a stroke.

Tumor Necrosis Factor Alpha (TNF- α)

Increased serum and cerebro-spinal fluid levels of TNF- α have been found in patients 24 hours, 1 week, and 2 weeks after a stroke, and these increases correlate with infarct volume and severity of neurological impairment (Zaremba J 2001). However, previous reports suggest that TNF- α has a dual role in brain injury (Hallenbeck JM 2002). Blockade of TNF- α actions reduced infarct volume after permanent middle cerebral artery occlusion in BALB/C mice with the dimeric type I soluble TNF receptor, which binds to TNF- α and antagonizes its action (Nawashiro H 1997a). In contrast, TNF- α pretreatment was neuroprotective against permanent middle cerebral artery occlusion in BALB/C mice with reduction of infarct size, macrophages, and CD11b-positive neutrophils (Nawashiro H 1997b). In addition to these observations, pentoxifylline, an anti-inflammatory agent, attenuated damage of a stroke via the dual role of TNF- α . Pentoxifylline treatment increased serum levels of TNF- α , but not IL-1 β and IL-6, and dose dependently prevented the occurrence of spontaneous brain damage by reducing macrophage infiltration into the lesion in SHRSP (Ban C 2004), suggesting a protective role of TNF- α . On the other hand, pentoxifylline reduced brain edema in a rat model of transient focal cerebral ischemia through a decline in TNF- α production (Vakili A 2011), suggesting a deleterious role of TNF- α . Based on crucial evidence that implicate TNF α as a mediator of acute brain damage, a number of pharmacological strategies have been followed by different investigators to either inhibit the synthesis or to neutralize the action of

TNF α and to assess the effect of such treatments on the outcome of ischemia and trauma. The pharmacological approaches that have been applied to improve the outcome after brain injury were based on: (a) inhibition of TNF α synthesis of low molecular weight molecules; and (b) neutralization of the biological effect of TNF α by proteins such as specific antibodies or binding proteins. Although anti-TNF- α strategies have proved beneficial in other clinical settings such as inflammatory bowel disease, there are no clinical trials of anti-TNF- α agents in strokes. Further studies are therefore required to clarify the role of TNF- α in strokes.

MCP-1

CC chemokine ligand (CCL2) is known as MCP-1 and is a potent mononuclear cell attractant. MCP-1 is synthesized by several cell types, such as monocytes/macrophages, T-lymphocytes, smooth muscle cells, endothelial cells, and even cerebrovascular endothelial cells. Expression of MCP-1 is upregulated by inflammatory cytokines. Serum levels of MCP-1 are high in patients with ischemic strokes and myocardial infarction (Arkeyalan A 2005), which might be interpreted as a stroke-induced increases in inflammatory events. It is reported that plasma levels of MCP-1 were elevated in patients with essential hypertension in the absence of other diseases (Madej A 2005). The MCP-1-deficient mice model is a unique model to elucidate the role of macrophages in a stroke (Huges PM 2002). Compared with control mice, infarct volume was smaller in MCP-1-deficient mice 24 hours after middle cerebral artery occlusion, and a reduction of phagocytic macrophage accumulation within infarcts and the infarct border in MCP-1 deficient mice 2 weeks after middle cerebral artery occlusion. In addition, MCP-1 deficient mice produced less IL-1 β in ischemic tissue. This means that MCP-1 and IL-1 β are key factors of macrophages in stroke lesions.

Adipokines

Obesity is also recognized as a risk factor for a stroke, because obesity is associated with hypertension and inflammation via secretion of adipokines, such as adiponectin, leptin, Resistin, adipisin, plasminogen activator inhibitor-1, and inflammatory cytokines (Mathieu P 2009, Yiannikouris A 2010). It is well known that macrophage infiltration into adipose tissue induces inflammation in adipose tissue and influences these adipokine secretions (Bouloumié A 2005). The most commonly studied adipocytokines are leptin and adiponectin. There are a lot of reports about the association of leptin and adiponectin with strokes, and leptin and adiponectin show differential association patterns with ischemic strokes (Kim BJ 2012). It is reported that higher leptin levels and lower adiponectin levels were found in stroke patients (Gerdes S 2012). On the other hand, there is controversial reports that adiponectin, but not leptin, levels are recognized as a predictor of the risk for a stroke (Pruger C 2012), or that leptin, but not adiponectin; levels are recognized as a predictor of the risk for strokes in men, but not women (Söderberg S 2009). It is not clear whether adiponectin and leptin are useful predictors of strokes in obese subjects; however, adiponectin and leptin might directly influence stroke incidence. It is reported that leptin stimulates macrophages and that adiponectin suppresses it. Leptin increases the mRNA and protein levels of IL-1 β , IL-6, IL-

12, TNF- α , cyclooxygenase-2, and MCP-1 in macrophages and endothelial cells (Loffreda S 1998). Adiponectin inhibits pro-inflammatory signaling in human macrophages (Folko EJ 2009) and promotes macrophage polarization toward an anti-inflammatory phenotype (Ohashi K 2010). Adiponectin also increases IL-10, an anti-inflammatory cytokine, as well as mRNA expression in human monocyte-derived macrophages (Kumada M 2004). In addition, both adiponectin and leptin receptors are expressed in the brain, suggesting that these adipokines might be directly associated with a stroke (Thundiyil J 2012).

ANTI-INFLAMMATORY STRATEGIES

There are several reports that treatment with drugs that have anti-inflammatory properties can prevent strokes not only in animal models, but also in humans.

Statins

Rosuvastatin treatment significantly delayed the onset of a stroke and attenuated the transcription of inflammatory biomarkers (Sironi L 2005). Clinical studies using statins already use inflammatory events as endpoints for stroke prevention. In healthy persons without hyperlipidemia but with elevated high-sensitivity CRP levels, rosuvastatin, which lowered high-sensitivity CRP as well as cholesterol levels, reduced the incidence of strokes and myocardial infarction by 50% relative to placebo (Ridker PM 2008). A meta-analysis of statin trials showed that statins might reduce the incidence of all strokes by decreasing LDL-cholesterol without increasing the incidence of hemorrhagic strokes (Amarenco P 2004). In addition to cholesterol dependent effects, cholesterol-independent effects of statins on strokes have also been recognized (Vaughan CJ 2003). However, statin treatment increases the risk of hemorrhagic strokes in patients with a history of cerebrovascular disease, even though it also clearly decreased the risk of an ischemic stroke (Vergouwen MD 2008). Therefore, patients undergoing statin treatment should be carefully monitored to avoid achieving very low levels of cholesterol, which are known risks for hemorrhagic strokes (Puddey IB 1996).

Thiazolidinediones

Thiazolidinediones, including rosiglitazone and pioglitazone, are peroxisome proliferator activated receptor- $\gamma\gamma$ (PPAR- γ) agonists used in the treatment of type 2 diabetes. A systemic review showed that 6 Mediators of Inflammation rosiglitazone and pioglitazone were similarly effective in reducing infarct volume and protecting neurologic function in a rodent model of focal or global cerebral ischemia (White AT 2010). Pioglitazone delayed the onset of a stroke by improving vascular endothelial dysfunction and brain inflammation in SHRSP. Pioglitazone suppressed macrophage infiltration, MCP-1 and TNF- α gene expressions in the brain (Nakamura T 2007). Rosiglitazone induced upregulation of CD36 in macrophages and enhanced the ability of microglia to phagocytose red blood cells, which helped to improve hematoma resolution, and improved functional deficits in an intracerebral hemorrhage mouse

model (Xhao H 2009). In humans, the PROspective pioglitAzone Clinical Trial In macroVascular Events (PROACTIVE) (Dormandy JA 2005) showed that pioglitazone significantly reduced the risk of a recurrent stroke in high-risk patients with type 2 diabetes (Wilcox R 2007). On the other hand, one report showed that compared with pioglitazone, rosiglitazone was associated with an increased risk of a stroke, heart failure, and all-cause mortality and an increased risk of the composite of acute myocardial infarction, strokes, heart failure, or all-cause mortality in patients of 65 years or older (Graham DJ 2010).

Other Inflammatory Drugs

Low-dose acetylsalicylic acid (aspirin) also delayed the onset of a stroke in SHRSP via suppression of inflammation. Aspirin reduced salt induced macrophage accumulation and MMP-9 activity at the stroke-negative area in the cerebral cortex of SHRSP (Ishizuka T 2008). Frequent aspirin use might also confer a protective effect for the risk of strokes in humans (Tymianski M 2011). Terutroban, a specific thromboxane/prostaglandin endoperoxide receptor antagonist, decreased cerebral mRNA expressions of IL-1 β , transforming growth factor- β , and MCP-1 and increased survival in SHRSP. These effects were similar to rosuvastatin and aspirin (Gelosa P 2010). The Prevention of cerebrovascular and cardiovascular Events of ischemic origin with terutroban in patients with a history of ischemic strokes or transient ischemic attack (PERFORM) study was started in February 2006 (Bousser MG 2009). Recently, it was reported that PERFORM study did not meet the predefined criteria for non-inferiority, but showed similar rates to terutroban and aspirin for the primary endpoint, such as a composite of fatal or nonfatal ischemic strokes, fatal or nonfatal myocardial infarction, or other vascular death (Bousser MG 2011). These reports indicate that antiplatelets agents, which also have anti-inflammatory properties, could suppress inflammation and prevent the onset of a stroke.

Inflammation and Ischemic Tolerance

Inflammatory and immune responses play important roles following an ischemic stroke. Inflammatory responses contribute to damage and also contribute to repair. Injury to tissue triggers an immune response. This is initiated through activation of the innate immune system. There is microglial activation in a stroke. This is followed by an influx of lymphocytes and macrophages into the brain, triggered by the production of proinflammatory cytokines. This inflammatory response contributes to further tissue injury. There is also a systemic immune response to a stroke, and there is a degree of immunosuppression that may contribute to the stroke patient's risk of infection. This immunosuppressive response may also be protective, with regulatory lymphocytes producing cytokines and growth factors that are neuroprotective. The specific targets of the immune response after a stroke are not known, and the details of the immune and inflammatory responses are only partly understood. The role of inflammation and immune responses after a stroke is twofold. The immune system may contribute to the damage after a stroke, but may also contribute to repair processes. The possibility that some of the immune responses after a stroke may be neuroprotective is

exciting and suggests that the deliberate enhancement of these responses may be a therapeutic option.

The suppression of inflammation appears to be the means by which ischemic preconditioning protects against a stroke. It is known that a sublethal ischemic event confers protection against subsequent lethal ischemia, in various organs, including the brain (Dhodha VK 2004). In experimental studies, animals that have been subjected to preconditioning have reduced inflammation after a subsequent ischemic challenge and reduced expression of inflammatory molecules (Bowen KK 2006). These changes are thought to be associated with changes in expression of genes such as hypoxia inducible factor 1 (HIF1) (Bernaudin M 2002, Dhodha VK 2004). In summary, it appears that immune suppression after a preconditioning ischemic episode prevents the acute harmful immune response after a subsequent ischemic episode. There is evidence that inflammation participates in tissue damage in strokes, and this is brought about by the activation of the innate immune system. Immunosuppression after a stroke has occurred may be too late to reduce this damage, although further work is required. After the acute injury of a stroke, there appears to be a naturally occurring state of immunosuppression, during which infection can occur. This immunosuppression appears to be due, in part, to circulating T cells. There is evidence that the immune system, possibly through such T cells, but also by other types of T cells, may be able to assist in neural repair. There is some animal work that suggests that tolerization to brain antigens improves outcomes after a stroke. Thus, immune and inflammatory responses after a stroke are both good and bad. Therapeutic possibilities based on this data include the early use of antibiotics to prevent infection (currently undergoing clinical trial), inhibition of the early inflammatory/immune response, although it is perhaps likely, that doing so after the stroke has occurred may be too late, and perhaps enhancing protective immune responses to speed neural repair.

CONCLUSION

In conclusion, in the presented work, we sought to provide a brief overview of the current understanding of inflammatory mechanisms involved during an acute ischemic stroke and neuroprotective agents that can curtail neuroinflammation and could have utility in the treatment of a stroke (see Table 1). As discussed, evidence suggests that post-ischemic oxidative stress and inflammation contribute to brain injury and to the expansion of the ischemic lesion. On the other hand, an adequate adaptive immune response after acute brain ischemia also plays an important role in response to ischemic injury as shown by the tremendous potential of Treg cells to prevent secondary infarct growth by counteracting the production of proinflammatory cytokines and by modulating the activation of lymphocytes and microglia in the ischemic brain (Liesz A 2009). These results provide new insights into the immunopathogenesis of acute ischemic strokes and could lead to new approaches that involve immune modulation using Treg cells. To date, 1,026 drugs have been tested in various animal models, of which 114 underwent clinical evaluation (De la Ossa NP 2007). The greater part of the agents studied until now have failed. Consequently, rt-PA remains the only agent shown to improve stroke outcomes in clinical trials, despite the many clinical trials conducted. However, its use is limited by its short therapeutic window (three hours), by its

complications derived essentially from the risk of hemorrhage, and by the potential damage by R/I injury. Because of these drawbacks the optimum treatment of cerebral focal ischemia remains one of the major challenges in clinical medicine.

ABSTRACT

The translation of neuroprotective agents for ischemic stroke from bench-to-bedside has largely failed to produce improved treatments since the development of tissue plasminogen activator (tPA). One possible reason for lack of translation is the failure to acknowledge the greatest risk factor for stroke, age, and other common comorbidities such as hypertension, obesity, and diabetes that are associated with stroke. In this chapter, we highlight both mechanisms of studying these factors and results of those that have been addressed.

We also discuss the potential role of other lifestyle factors associated with an increased stroke risk, such as sleep fragmentation and/or deprivation. Furthermore, many proposed therapeutic agents have targeted molecular mechanisms occurring soon after the onset of ischemia despite data indicating delayed patient presentation following ischemic stroke.

Modulating inflammation has been identified as a promising therapeutic avenue consistent with preliminary success of ongoing clinical trials for anti-inflammatory compounds such as minocycline. In this chapter, we review the role of inflammation in stroke and in particular, the role of inflammatory cell recruitment and macrophage phenotype in the inflammatory process. Emerging evidence indicates an increasing role of neuro-immune crosstalk, which has led to increased interest in identification of peripheral biomarkers indicative of neural injury. It is our hope that identification and investigation of factors influencing stroke pathophysiology may lead to improved therapeutics.

INTRODUCTION

Acute ischemic stroke remains a condition of high morbidity and mortality. Until now, the only established therapy has been intravenous (IV) tissue-type plasminogen activator (tPA). Only 3–10% of patients with acute ischemic stroke receive this treatment. On the basis of data from part 3 of the European Collaborative Acute Stroke Study (ECASS III), the time window for beneficial treatment of ischemic stroke with IV tPA has been extended from 3 to 4.5 h after the onset of stroke symptoms. Beyond that window of opportunity, and additionally to IV treatment, interventional stroke therapy has assumed an important role for the treatment of acute ischemic stroke. Currently, new promising pharmacological and mechanical treatment options are being established as routine procedures to achieve a further improved outcome for stroke patients.

The main challenge in stroke therapy is how to rescue patients who have survived the ischemic insult, considering that by the time they are evaluated, the majority might have passed the 3-h window in which to receive t-PA therapy. Therefore, the prime issues are: i) how to extend the window of treatment; ii) how to minimize the effect of reperfusion injury, considering that the damaging effect due to reperfusion sometimes could be greater than that due to ischemia itself; iii) how to reduce the risks associated with t-PA therapy beyond 3 h; and iv) how to regenerate infarcted brain areas to regain neurological function. New advances that combine the basic understanding of pathobiology of the disease and translational research, including drug delivery approaches and surgical interventions could address the complex issues associated with stroke therapy.

Stroke is a leading cause of death, long-term disability, and socioeconomic costs, highlighting the urgent need for more effective treatments. Intravenous administration of tissue plasminogen activator (t-PA) is the only FDA-approved therapy to re-establish cerebral blood flow. However, because of increased risk of hemorrhage beyond 3 h post stroke, few stroke patients (1–2%) benefit from t-PA; t-PA, which has neurotoxic effects, can also aggravate the extent of reperfusion injury by increasing blood-brain barrier permeability. An alternative strategy is needed to extend the window of intervention, minimize damage from reperfusion injury, and promote brain repair leading to neurological recovery. Reactive oxygen species (ROS), generated soon after ischemia and during reperfusion and thereafter, are considered the main mediators of ischemic injury. Antioxidant enzymes such as catalase, superoxide dismutase, etc. can neutralize ROS-mediated injury but their effective delivery to the brain remains a challenge. In this chapter, we review various therapeutic approaches including surgical interventions, and discuss the potential of nanoparticle-mediated delivery of antioxidants for stroke therapy.

Stroke is a sudden loss of brain function resulting from interference with the blood supply to the central nervous system (CNS). Normal cerebral blood flow (CBF) is approximately 50–60 ml/100g/min. The reduction in CBF below 20 ml/100g/min results in an electrical silence and less than 10 ml/100g/min causes irreversible neuronal injury (Hakim M. 1998, Jones T. H. 1981). Lack of blood circulation to the brain deprives neurons of necessary glucose and

oxygen. Neurons are the impulse transmitters; hence they require constant supply of energy. Up to 85% of all strokes are of ischemic origin, with most attributable to blockage of one or more cerebral artery by blood clots, with resulting reduction in cerebral perfusion. The remaining stroke cases are hemorrhagic, involving either intracerebral or subarachnoid hemorrhage.

MECHANISMS OF NEURONAL INJURY AND THE THERAPEUTIC POSSIBILITIES

Cerebral ischemia results in a number of hemodynamic, biochemical, and neurophysiological alterations (Ostrowski R. P. 2006). A series of complex acute, subacute and chronic events occur after the incidence of stroke and reperfusion (Jean W. C. 1998). Ischemic injury involves energy failure, loss of cell ion homeostasis, acidosis, increased intracellular calcium excitotoxicity, free radical-mediated toxicity, and pathological permeability of the blood-brain barrier (BBB). Free radicals, specifically reactive oxygen species (ROS) that are generated soon after ischemia, as well as in later stages of ischemic reperfusion (e.g., by inflammatory cells), are the fundamental mediators of reperfusion injury.

The development of hypoxic-ischemic neuronal injury is significantly influenced by the release of excitatory neurotransmitters, primarily glutamate and aspartate in the brain. This process is called excitotoxicity and is activated by depletion of cellular energy stores. Glutamate, normally stored inside the synaptic terminals, is released in the extracellular space in a depleted energy state, which then results in the opening of calcium channels associated with N-methyl- D aspartate (NMDA) and alpha-amino-3-hydroxy-5-methyl-4-isoxanole propionate (AMPA) receptors. This leads to an influx of calcium, sodium and chloride ions and efflux of potassium ions. (Siesjo B. K. 1989, Hademenos G. J. 1997, Garcia J. H. 1994). The influx of calcium is responsible for the activation of a series of destructive enzymes such as proteases, endonucleases and lipases that allow release of cytokines and other inflammatory mediators, resulting in the loss of cellular integrity (Siejo B. K. 1981, Becker K. J. 1998). Inflammatory mechanisms play an important role in tissue injury by inducing the rapid production of many different inflammatory mediators. Within 30 minutes after ischemia and reperfusion, leukocytes recruited to the ischemic area activate mediators of inflammation such as oxygen free radicals, cytokines, and nitric acid.

A vast amount of data implicates oxygen-derived free radicals (especially superoxide and hydroxyl radicals) and high-energy oxidants (such as peroxynitrite) as mediators of inflammation in ischemia/reperfusion injury (Cuzzocrea S. 2001). Free radicals are highly reactive molecules generated predominantly during cellular respiration and normal metabolism. Imbalance between cellular production of free radicals and the ability of cells to defend against them is referred to as oxidative stress (Valko M. 2007).

After brain injury by ischemic stroke, the production of ROS dramatically increases, leading to tissue damage via several different cellular, molecular pathways, and mechanical pressure (Figure 4.1).

ROS can cause damage to cellular components such as lipids, protein, and nucleic acids, leading to subsequent cell death (Janardhan V. 2004). Damage can become more widespread due to weakened cellular antioxidant defense systems in ischemia.

Figure 4.1. Schematic showing different types of stroke and cascade of events following ischemia.

ROS are the major stimulators of inflammatory cytokine production (such as interleukin-1, tumor necrosis factor- α , and interferon- γ) and protease secretion by microglia, leukocytes, and resident cells of the neurovascular unit (Haddad J. J. 2002). As these neuroinflammatory mechanisms become activated, alterations in cytokine profiles, adhesion-molecule expression, and tight-junction components mediate further vascular leakage. Significant evidence exists suggesting that ROS are involved in every fundamental physiological step that leads to neuronal death (Cao W. 1988) and thus are considered an important target in developing an effective stroke therapy (Juurlink B. H. 1997).

Following the onset of ischemic stroke, cerebral blood flow is disrupted throughout the affected region of the brain. Blood flow disruption to the tissue is not uniform due to the presence of collateral circulation resulting in a flow gradient. Consequently, a “core” region of infarct develops in which flow is severely reduced, often approximating upwards of a 90% decrement, and tissue undergoes necrosis within minutes as insufficient adenosine triphosphate (ATP) is present to maintain homeostatic ionic gradients and metabolic functions (Astrup J. 1977). Surrounding this core region in which blood flow is severely reduced is the “penumbra”, a tissue distribution in which flow is less severely reduced and remains typically around 35% of baseline flow (Astrup J. 1977). Characterized by normal cellular membrane potential but a disruption in the ability for normal action potential firing, tissue initially residing within the penumbral region progresses to cellular death, ultimately resulting in an expanded core lesion without restoration of cerebral blood flow (Lo E. H. 2008). As such, therapeutic development has focused on achieving reperfusion via tissue plasminogen activator (tPA) and/or restoring homeostasis via administration of ‘neuroprotective’ pharmacologic agents intended to disrupt the ischemic injury cascade.

Current research in stroke has focused on developing neuroprotective therapies that target many mechanisms involved in stroke pathophysiology.

Figure 4.2. Ischemic cascade leading to cerebral damage. Ischemic stroke leads to hypoperfusion of a brain area that initiates a complex series of events. Excitotoxicity, oxidative stress, microvascular injury, blood-brain barrier dysfunction and postischemic inflammation lead ultimately to cell death of neurons, glia and endothelial cells. The degree and duration of ischemia determines the extent of cerebral damage.

Studies from animal and cell models have greatly expanded our knowledge in this field and form the basis of clinical trials of neuroprotective therapies. Results have been variable; it is very likely that no single therapy will be satisfactory, and that multiple agents working through different mechanisms or novel agents that target more than disease mechanism may offer the best hope for a future neuroprotective therapy. In this chapter, we address several disease mechanisms of pathogenesis in stroke, along with some examples of therapies targeting each of these mechanisms.

CURRENT STATUS OF NEUROPROTECTANT DEVELOPMENT: DRUG DEVELOPMENT SHORTCOMINGS

Investigation of neuroprotection and the associated concepts have gone through various periods of apparent focus as described by Lo previously (Lo E. H. 2008). Early studies, initiated by Astrup and colleagues, focused on understanding the effect of ischemia produced across a range of cerebral blood flow measurements on neurophysiology and electrical conduction (Astrup J. 2008).

The second phase of investigation sought to identify molecular mechanisms of injury with an emphasis on the acute period of injury. Following molecular biology studies was the

discovery and implementation of numerous imaging modalities in both preclinical and clinical studies for assessing both changes in blood flow and the evolution of both the penumbra and infarct core (Lo E. H. 2008). While these various developments have provided much insight and utility in both preclinical and clinical studies, successful translation of a neuroprotectant from bench-to-bedside has yet to occur despite identification of over 1000 “successful” neuroprotectants in preclinical studies and initiation of over 100 clinical trials (O’Collins V. E. 2006).

The reasons for lack of translation and failure are presently unknown but clear discrepancies exist between preclinical models and the clinical population most commonly afflicted by ischemic stroke. These include the age and general health of the population being studied as well as the time point of treatment initiation. Similarly, the endpoints frequently used in preclinical and clinical studies are often different. Furthermore, the vast majority of preclinical work has been conducted in rodents, species that are more distant phylogenetically from the human population in comparison to nonhuman primates. Nonhuman primates more closely resemble humans in vascular anatomy, experience striatal damage following ischemic stroke more comparably to the human, and are gyrencephalic in nature like humans (Fukuda S. 2003). Consequently, nonhuman primates represent perhaps the most ideal preclinical model, but are frequently not utilized due to cost, lack of availability, and expertise required for care and use. For these reasons, nonhuman primate models are not discussed further. The following sections elaborate on these concepts in an attempt to convey the contribution of common comorbidities seen in the clinical population to stroke risk and outcome. Furthermore, the potential impact of other lifestyle factors such as sleep fragmentation and/or deprivation, often related to an altered sleep-wake cycle by something such as shift work, is discussed.

In treating acute ischemic stroke, two primary strategies are followed: 1) limiting the ischemic insult by early reperfusion and 2) interfering with the pathobiochemical cascade leading to ischemic neuronal damage.

In developing an effective therapy, one must also weigh the deleterious consequences of reperfusion injury versus the effects of delay in resuming blood supply to the brain (Wagner K. R. 2004).

Within an hour of ischemia, two layers of cerebrovascular tissue develop: the inner core displaying necrosis of both neuronal as well as supporting glial elements, and the outer layer of less severe ischemia called the ischemic penumbra. The cells within the ischemic penumbra can be recovered if timely therapeutic intervention is administered. The size of the ischemic penumbra (portion of the brain that can be rescued) diminishes with time, as the infarct core progressively becomes hypoperfused tissue that cannot be rescued following reperfusion. Ischemic damage in the penumbra, however, is reversible and is the target of rescue via re-establishing blood flow (Fisher M. 2004).

DRUGS USED IN ACUTE STROKE THERAPY

Drug therapy is a relatively recent approach to the treatment of stroke, and a large amount of research is focused on finding effective new drugs that can minimize stroke damage. The most relevant drugs evaluated for acute stroke therapy are summarized in Table 4.1.

Table 4.1. Drugs used in endovascular therapy for acute stroke

Group	Drug	Effect
Drugs to improve blood flow	Heparin Abciximab Ancrod	Antithrombotic Antiplatelet Fibrinogen depleting
Thrombolytics	Streptokinase Urokinase Prourokinase Alteplase Retepase Tenecteplase Tissue plasminogen activator Alfimeprase BB10153 Desmoteplase	Plasminogen activators Direct acting fibrinolytics
New drugs under evaluation	V10153 Microplasmin	

PLASMINOGEN ACTIVATORS

Plasminogen activators are the primary drugs used as thrombolytic agents in acute stroke therapy. These drugs act by converting plasminogen into plasmin. Plasmin unlocks fibrinogen, fibrin monomers and cross-linked fibrin (as found in a thrombus) into fibrin degradation products (Lisboa R. C. 2002).

Streptokinase a clot buster bind to plasminogen and the streptokinase/plasminogen complex then serves as a plasminogen activator. It is a protein derived from group CS-hemolytic streptococci, which showed significant rates of ICH and systemic hemorrhage (Cornu C. 2000); thus, it is no longer used for acute stroke therapy; rather, Urokinase, a serine protease with a plasma half-life of 14 min, is used (Lisboa R. C. 2002). The randomized trial of intra-arterial infusion of urokinase within 6 h of middle cerebral artery stroke: the middle cerebral artery embolism local fibrinolytic intervention trial (MELT), suggested that intra-arterial fibrinolysis has the potential to increase the likelihood of excellent functional outcome (Ogawa A. 2007). Prourokinase (r-prourokinase) is the proenzyme precursor of urokinase. Despite the favorable results in the PROACT (Prolyse in Acute Cerebral Thromboembolism) I and II trials (de Zoppo D. J. 1998, Furlan A. 1999), the FDA did not approve its use in IA stroke therapy.

Alteplase (recombinant human tissue-type plasminogen activator; rtPA) is a serine protease with a plasma half-life of 3.5 min. This short half-life and the limited penetration of the clot, because of strong binding with surface fibrin, delay recanalization and increase the risk of recurrent occlusion. By the administration of heparin or antiplatelet drugs, reocclusion may be reduced.

Moreover, rtPA seems to have some neurotoxic properties, including activation of metalloproteinases, which may result in increased blood–brain barrier permeability leading to

cerebral hemorrhage and edema, as well as amplification of calcium currents through the N-methyl-D-aspartate receptor. This leads to excitotoxicity and neuronal death (Kaur J. 2004). Nevertheless, rtPA represents the first line therapy in the treatment of acute ischemic stroke. More recently licensed plasminogen activators are variants of tPA. These include Reteplase, a truncated tPA variant with a longer half-life and Tenecteplase, a bioengineered tPA variant. Because of their longer half-lives, Reteplase and Tenecteplase can be given as a bolus injection, thereby simplifying administration (Llevadot J. 2001). A case study reported 84% recanalization and no ICH with IA Reteplase in combination with mechanical thrombolysis (Qureshi A. 2002). A pilot clinical trial with Tenecteplase, was terminated owing to symptomatic and asymptomatic ICHs (15% and 23%, respectively) (Haley E. C. 2005). Direct fibrinolytics and new fibrinolytic agents currently under development were built upon advances of tPA derivatives developed to produce less bleeding (Mellot M. J. 1995).

Alfimeprase (ARCA Biopharma Broomfield, CO, USA), a recombinant, truncated form of fibrolyase, has been developed to accelerate lysis. It is designed to dissolve clots by directly degrading fibrin when delivered through a catheter directly into the thrombus and is inactivated locally by circulating alpha-2 macroglobulin. Because there is no need for plasmin generation, alfimeprase has the potential to degrade fibrin more rapidly than tPA. This should result in faster recanalization and lower hemorrhagic risk (Deitcher S. R. 2005). Nevertheless, alfimeprase failed to meet the key efficacy end points of revascularization in the phase II trial CARNEROS-1 (Proof-of-Concept Study of the Safety and Efficacy of Alfimeprase to Rapidly Open Arteries and Restore Brain Function Following a Stroke). The full results of this trial have not yet been published.

BB10153 (British Biotech, Oxford, England), a variant form of plasminogen, has the plasminogen activator cleavage site replaced with a thrombin cleavage site. Like plasminogen it binds to fibrin and gets converted to plasmin by fibrin-bound thrombin. In a phase II dose-escalation study 34% of patients achieved complete lysis in the infarct-related artery. There were no intracranial bleeds (Gibson C. M. 2006) and based on these data, BB10153 is undergoing continued investigation. Desmoteplase (Paion, Aachen, Germany), a recombinant analog of the full-length plasminogen activator isolated from the saliva of the vampire bat, demonstrated safety in the Desmoteplase in Acute Ischemic Stroke (DIAS), Dose Escalation of Desmoteplase for Acute Ischemic Stroke (DEDAS), and DIAS-II trials (Furlan A. J. 2006). A new trial (DIAS-III) was stopped because of lack of efficacy in the desmoteplase-treated patients. The thrust of this study was to determine whether the window for fibrinolytic therapy could be extended beyond 3 h (Hacke W. 2005).

The success of plasminogen activators is, at least in part, highly dependent on the amount of plasminogen in the thrombus. Newer drugs do not depend on the availability of plasminogen.

Ancrod (Viprinex; Neurobiological Technologies, Emeryville, CA, USA) is a defibrinogenating agent derived from the venom of the Malayan pit viper. By defibrinogenating blood an anticoagulant effect is promoted. To study the safety and efficacy of ancrod in patients with acute ischemic stroke administered within 6 h of stroke onset, the Ancrod Stroke Study was performed. No significant difference in overall mean scores on the Scandinavian Stroke Scale could be demonstrated. Those patients with ancrod-induced 6-h fibrinogen levels of 130 mg/dL or less had a marginally significantly better neurological outcome on the Scandinavian Stroke Scale, mortality, and Barthel Index than ancrod-treated patients with higher fibrinogen levels (The Ancrod Stroke investigators, 1994).

V10153 (Vernalis, Winnersh, UK) is a novel modified recombinant variant of human plasminogen, which is activated to plasmin by thrombin. Thrombin, as the key enzyme involved in blood clot formation, is utilised to initiate clot destruction (Davson K. M. 1994). V10153 selectively induces lysis of newly formed clots, which should result in a reduced risk of hemorrhage. The V10153 Acute Stroke Thrombolysis Trial (VASTT) was a phase II dose-escalation multicenter study. The trial has been halted because of significant hemorrhagic complications. The trial enrolment is closed and data are currently being analyzed.

Microplasmin (ThromboGenics, Heverlee, Belgium) is a truncated form of plasmin that is more resistant to antiplasmin. In a rabbit stroke model, IV microplasmin infusion resulted in a high rate of clot lysis without increasing the rate of ICH (Lapchak P. A. 2002). These findings were confirmed in the MITI-IV (Microplasmin in Treatment of Ischemic Stroke-IntraVenous) trial, a phase II multicenter, randomized, double-blinded, placebo-controlled ascending-dose clinical trial. Data are yet to be published.

ADJUVANT DRUGS

Because fibrinolytic agents also have prothrombotic properties, early reocclusion has been demonstrated in 34% of the patients treated with IV rtPA (Alexandrov A. V. 2002). Therefore, the adjuvant use of antithrombotic agents is common practice. IV heparin for systemic anticoagulation during the periprocedural phase of endovascular stroke therapy is controversial. The potential advantages, including augmentation of the thrombolytic effect, prevention of acute reocclusion and reduction in the risk of catheter-related embolism, have to be weighed against the potentially increased risk of ICH when heparin is combined with a thrombolytic agent (delzeppo G. J. 1998). The use of glycoprotein (GP) IIb/IIIa antagonists, such as ReoPro (abciximab – an intravenous platelet aggregation inhibitor, is a monoclonal antibody directed against the platelet glycoprotein GP IIb–IIIa receptor), Integrilin (eptifibatide), or Aggrastat (tirofiban) in ischemic stroke remains investigational. In pilot studies, no major ICH was seen in combination with standard rtPA therapy (Pancioli M. 2008). Conversely, the AbESTT (Abciximab in Emergent Stroke Treatment) Trial-II, a phase III study, evaluating the safety and efficacy of abciximab in acute ischemic stroke, including patients who awoke with stroke symptoms, was permanently stopped owing to a high rate of intracranial hemorrhage in the abciximab-treated patients (Adams H. P. 2008). The data for the use of GP IIb/IIIa inhibitors in conjunction with intraarterial thrombolysis are limited to case reports. The number of cases with symptomatic ICH varied between 0 and 23% (Nogueira R. J. 2008)

ENDOVASCULAR THERAPY OF ACUTE STROKE

The relatively high haemorrhage rates, in combination with the low complete recanalization rates, demonstrate the limitations of treatment solely with pharmacological agents. Especially in carotid terminus or basilar artery occlusions with large clot burden, the procedure takes time and may not achieve meaningful recanalization. Platelet-rich clots, old clots and calcified clots or fat emboli cannot be addressed. These factors substantiate the

assumption that faster and more complete reperfusion will lead to better long-term outcomes for acute stroke patients. Endovascular therapy promises higher recanalization rates because of the obvious advantages over IV rtPA, which are site specific, reduction of drug amount and potentially longer treatment windows.

Nevertheless, the potential benefit of endovascular therapy must be weighed against the potential risk of the procedure. Intraarterial (IA) stroke therapy has been associated with a 5–7% risk for clinically significant procedural complications (delzeppo G. J. 1998, Furlan A. 1999) and a 6–15% risk for symptomatic ICH (Smith W. S. 2002). Patients with minor strokes, who are treated with IV rtPA, have an 82% chance of a good outcome and the risk of symptomatic hemorrhage and death is 3% and 1%, respectively (The NINDS Stroke study Investigators, 2005).

Such patients are quite unlikely to benefit from endovascular stroke therapy, as they often show no vessel occlusion on cerebral angiograms (Fisher U. 2005). Most stroke centers offer IA stroke therapy only to patients with major strokes. Different strategies of endovascular therapy are offered to reach reperfusion of occluded vessels in acute stroke. Most techniques focus on removing and dissolving the occlusive thrombus to reestablish antegrade flow, but some use the collateral vessel system of the brain to augment flow retrogradely. The different interventional methods are summarized in Table 4.2.

Table 4.2. Strategies of endovascular stroke therapy

Strategies of endovascular stroke therapy			
Interventional method	Endovascular device used	Reperfusion	
		Ante-grade	Retro-grade
Intraarterial thrombolysis	Microcatheter	X	
Mechanical thrombus disruption	Microguidewire, laser	X	
Percutaneous transluminal angioplasty	Microcatheter with balloon for dilatation	X	
Aspiration of thrombus	Guiding catheter	X	
Endovascular thrombectomy	Clot retriever	X	
Augmented fibrinolysis	Ultrasound	X	
Thrombus entrapment	Stent	X	
Temporary endovascular bypass	Stent		x
Flow augmentation	Balloon catheter		x
Transarterial or transvenous retrograde reperfusion	Balloon catheter		

INTRA-ARTERIAL THROMBOLYSIS

The major theoretic advantage of IA thrombolysis over IV thrombolysis is that microcatheter techniques allow direct access to the occluded intracranial vessel and by penetrating the thrombus with the microcatheter the fibrinolytic agent can be infused into the thrombus. This permits a smaller dose of fibrinolytic agent to reach a higher local concentration than reached by systemic infusion and ideally allows more complete recanalization. Additionally, complications from systemic fibrinolytic effects, including ICH, can theoretically be reduced. Thus, the treatment window for endovascular techniques can be extended beyond the typical IV window by 3–6 h, which is important because of the low number of patients who present during the 3-h time window. The first reports about IA administration of thrombolytic agents, mainly in the posterior circulation, were published in the 1980s. An overall recanalization rate of 60% and a mortality rate of 90% in nonrecanalized patients versus 31% in at least partially recanalized patients were found (Zeumer H. 1983, Hacke W. 1988). Multiple non-randomized case series reported successful use of IA thrombolysis. A review of patients treated with urokinase, showed recanalization rates of >75% when additional endovascular techniques (such as mechanical fragmentation of the thrombus, thromboaspiration, percutaneous transluminal angioplasty, and implantation of stents) were used (Nogueira R. J. 2008). Combined IV and IA thrombolysis Several studies have evaluated the feasibility, safety and efficacy of combined IV rtPA with IA thrombolysis in patients with acute stroke. This approach has the potential of combining the advantages of IV rtPA (fast and easy to use) with the advantages of IA therapy (directed therapy, titrated dosing, mechanical aids to recanalization and higher rates of recanalization), thus improving the speed and frequency of recanalization. In the Emergency Management of Stroke (EMS) Bridging Trial, no difference in the 7–10-day or 3-month outcomes between the IV rtPA or IV placebo followed by immediate intra-arterial therapy with rtPA group were found, but there were more deaths in the IV/ IA group (Lewandowski C. A. 1999). The Interventional Management of Stroke (IMS I) Study investigated a combined IV and IA approach to recanalization in patients with ischemic stroke (IMS study Investigators, 2004). The 90-day mortality rate in IMS I subjects (16%) was numerically lower, but not statistically different from the mortality rate of the placebo (24%) or rtPA treated subjects (21%) in the NINDS-rtPA-Stroke-Trial.

MECHANICAL THROMBECTOMY

When thrombolysis is ineffective or is not considered as a viable option, mechanical devices are used to recanalize the occluded cerebral vessel to restore the flow (IMS 2007). One such device, the Merci Retriever™ (Concentric Medical, Mountain View, CA), consists of a flexible corkscrew-shaped tapered nitinol wire with 5 helical loops that can be threaded in the thrombus, which is then removed by traction (Smith W. S. 2006). The first prospective study that examined a device-based treatment option for ischemic stroke showed a 43% recanalization rate with the device alone and a 64% recanalization rate with additional intraarterial administration of t-PA (Smith W. S. 2008). The Catch System™ (BALT Extrusion, Montmorency, France) is a tiny wire basket that retrieves the thrombus

(Brekenfeld C. 2008). Another useful new technique has been developed in which the clot is simultaneously aspirated from the vessel as it is being extracted. The Phenox Clot Retriever™ (Phenox, Bochum, Germany) consists of a highly flexible core wire compound resembling a pipe cleaner with perpendicularly oriented polyamide microfilaments that create an attenuated palisade. It is deployed distal to the clot and is slowly pulled back under continuous aspiration via the guiding catheter.

The BONnet™ (Phenox, Bochum, Germany) consists of a self-expanding nitinol braiding with polyamide filaments passing through the interior to enlarge the surface area and enable better fixation of the thrombus mass (Liebig T. 2008). The Penumbra System™ (Penumbra, Alameda, CA) has been FDA-approved as a dual approach to clot extraction using aspiration and debulking of the thrombus to reduce or eliminate the clot burden (Natrajan S. K. 2009, PPST 2009). The system includes reperfusion microcatheters that are connected to an aspiration pump through an aspiration tube. A separator is advanced and retracted within the lumen of the reperfusion catheter to debulk the clot, followed by clot retrieval with a ring device that engages the thrombus by capturing it in clasps with a cylinder that is then withdrawn. The recanalization rate is more than 80% and the device has an excellent safety profile (<3% procedural serious adverse events) (Struffert T. 2009). This system has the potential of reopening a vessel without the use of thrombolytics, thus offering dual options for recanalization via a single access platform, and decreases the need to blindly penetrate into the occluded vascular segment because it operates from the proximal end of the clot (Nogura R. G. 2009). Percutaneous transluminal angioplasty (PTA) is particularly useful in cases of atherothrombotic disease, in which the residual stenosis may reduce flow sufficiently to lead to rethrombosis (Abu Chebl A. 2005). PTA can be used alone or with subsequent thrombolytic therapy for distal embolization. The largest study of angioplasty for acute stroke showed that recanalization was achieved in 63.9% of thrombolytic-only treated patients, versus 91.2% in the combined thrombolytic plus PTA treatment group. Because of the risk of vessel rupture and distal embolization, this technique is generally reserved for patients whose flow cannot be restored by more conservative methods (Abu Chebl A. 2005). Interventional treatment of acute ischemic stroke with self-expanding stents for flow restoration has been shown to be an effective method for achieving re-canalization. In a prospective study, Stent-Assisted Recanalization in Acute Ischemic Stroke, 100% successful recanalization was demonstrated in 20 patients, with only 1 symptomatic hemorrhage. The disadvantage of this approach is the implantation of a permanent prosthesis and the need for continuous antiplatelet therapy (Levy E. I. 2009, Jahan R. 2010).

Several techniques are used for mechanical clot disruption. The most common is probing the thrombus with a microguide wire. This technique appears to be useful in facilitating chemical thrombolysis. Alternatively, a snare (e.g., Amplatz goose-neck microsnare, Microvena) can be used for multiple passes through the occlusion to disrupt the thrombus (Berguie M. 2006). A snare can also be used for clot retrieval, mostly in situations in which the clot has a firm consistency or contains solid material. Two devices that use laser technologies have been used to disrupt intracranial clots. The EPAR (Endovaxis, Belmont, CA, USA) is a mechanical clot-fragmentation device based on laser technology. The photonic energy is converted to acoustic energy at the fiberoptic tip through creation of micro cavitation bubbles, causing emulsification of the thrombus which is a mechanical thrombolysis and not a direct laser-induced ablation. In a pilot study with 34 patients, vessel

recanalization occurred in 61.1%. There were ICHs in 5.9% and the overall mortality rate was 38.2% (Berlis A. 2004).

The LaTIS laser device (LaTIS, Minneapolis, MN, USA) uses the slow injection of contrast material as a 'light pipe' to carry the energy from the catheter to the embolus. A safety and feasibility trial was stopped because the device could not be deployed to the level of the occlusion in 2 of the first 5 patients.

INTRA-ARTERIAL (IA) MECHANICAL THERAPIES

The limitations to IA lysis are related to clot characteristics. The response to the pharmacological agent may vary according to the source and type of clot. White platelet rich clots are more resistant to lytics than fresh red blood cell rich clots. De novo cardiac clots and paradoxical venous clots respond better than calcified clots from atherosclerotic plaques. The therapeutic approach concerning these limitations changed dramatically in 2004 with the US Food and Drug Administration approval of the first mechanical clot-retriever (Smith W. S. 2005). The mechanical fragmentation of a clot increases the surface area accessible to fibrinolytic agents thus increases the speed of thrombolysis. The use of chemical thrombolytics is lower, or can be avoided, particularly in patients with contraindications to thrombolytic therapy. The treatment window can be exceeded beyond the limit of 6–8 h. Clot-retrieval devices also may be more efficient in catching mature embolic clots and emboli composed of cholesterol, calcium or other debris from atherosclerotic lesions (Smith W. S., 2005 and 2008, Noguiera R. G. 2009).

SURGICAL INTERVENTIONS

Surgical reconstruction of the cervical carotid artery may be indicated in patients with transient ischemic attack but who are otherwise in good neurologic condition. Another option, microsurgical embolectomy of intracranial vessels, is an invasive procedure involving craniotomy, opening the occluded artery to remove the clot, and reperfusion of the affected area. However, because the procedure is performed through the subarachnoid space via a small craniotomy with a minimal skin incision, it is relatively safe. This can be a last therapeutic option for those patients who are ineligible to receive intravenous or intraarterial thrombolysis, or in the case of failed mechanical thrombectomy. Again, there is a restrictive time window of less than 6 hours from stroke onset for the intervention to be effective. Another surgical procedure utilized in ischemic stroke patients is brain decompression. In the case of major vessel occlusion, large cerebral infarcts is developed, commonly associated with rapidly progressing malignant cerebral edema (Hofmeijer J. 2004). This leads to compromised neuronal metabolism, decreased cerebral perfusion, and impaired oxygenation. In addition, shifting of intracranial contents and transtentorial herniation, is the leading cause of death in these patients (Hacke W. 1996). Because this kind of cerebral edema is refractory, i.e., not amenable to other forms of treatment, brain decompression is considered a therapy of last resort. Decompressive hemicraniectomy with duraplasty is a complex procedure in which a part of the skull vault is removed and the dura is opened to give more room for the

expanding brain. Then, a Silastic sheet, watertight Lyodura, or pericranial grafts are placed over the craniectomy for brain protection. This procedure has been shown to result in increased cerebral perfusion, better survival, improved neurological outcomes, and a reduction in the volume of the infarction (Adams H. P. 2007, Schwab S. 2007). Another, more invasive craniotomy involves resection of infarcted tissue and/or uncal resection. Resection of dead tissue makes room for reperfusion of live tissue in the affected area. Both types of procedures appear to yield satisfactory outcome results.

The disadvantages of the mechanical approaches include the difficulty of navigating devices into the intracranial circulation, excessive trauma to the vasculature (potentially leading to vasospasms, vessel dissection, perforation or rupture) and fragmented thrombus causing distal embolization into previously unaffected territories.

PERCUTANEOUS TRANSLUMINAL ANGIOPLASTY

The feasibility and high efficacy of percutaneous transluminal angioplasty (PTA) in acute stroke has been shown (Ueda T. 1997). Partial or complete recanalization could be achieved in 91% of patients treated with direct PTA versus 64% treated with thrombolytic therapy alone. ICH was seen in 3% versus 19%, and good outcome occurred in 73% versus 50% of the patients, respectively (Nakano S. 2002). 92% recanalization was achieved with the use of balloon angioplasty and adjuvant low-dose eptifibatide and/or thrombolytics with 42% good outcomes (Nogueira R. G. 2008). PTA may also be particularly useful in the cases of atherothrombotic disease, in which the residual stenosis may reduce flow sufficiently to lead to rethrombosis (Quereshi A. I. 2002).

ENDOVASCULAR THROMBOASPIRATION

The use of large 7 to 8-F guide catheter with syringe suction is a simple approach that has been used to remove occlusive thrombus and restore flow in symptomatic acute internal carotid artery occlusion. The guide catheter is slowly withdrawn to facilitate more complete removal of the thrombus (Breckenfield C. 2005). Suction thrombectomy or thromboaspiration through either a microcatheter or a guiding catheter may be an option for a fresh clot. Aspiration devices cause fewer embolic events and vasospasm, but can be difficult to navigate into the intracranial circulation.

The Penumbra System (Penumbra, Alameda, CA, USA) uses a microcatheter and a separator, which is advanced and retracted through the catheter to dislodge the clot and a suction device removes it. This system was initially tested in a pilot trial, where 23 subjects were enrolled. Recanalization before IA lysis was achieved in all treated cases (48%). Good outcome at 30 days was demonstrated in 45% of patients. The mortality rate was 45%. The use of adjunctive IA thrombolytic therapy was associated with a higher incidence of hemorrhage (Bose A. 2008).

The Angiojet (Possis Medical, Minneapolis, MN, USA) is an endovascular rheolytic thrombectomy device that combines local vortex suction, created by high-pressure saline jets, with mechanical disruption. The generated clot fragments are then sucked into the 4- or 5-F

access catheter, which is not flexible enough to allow its navigation into the intracranial arteries. The NeuroJet (Possis Medical) has been designed specifically for intracranial navigation. Unfortunately, vessel dissections and the inability to navigate through the carotid siphon were noted in a pilot study, and the trial was discontinued (Molina C. A. 2005).

ENDOVASCULAR THROMBECTOMY

Endovascular thrombectomy means the extraction of the thrombus with the help of an endovascular tool through a catheter, and should provide rapid recanalization and flow restoration with a reduced risk of distal embolic complications. It is used alone or in conjunction with thrombolytic drugs. The limitations of these devices are intracranial navigation and capture of thrombus within the tortuous cerebral vasculature, and the risk of vessel wall damage or perforation. Some of the devices grasp the thrombus and apply force proximally; others are basket like devices and use a distal approach to the clot.

The Merci Retrieval System (Concentric Medical, Mountain View, CA, USA) is a nitinol wire with an imprinted shape memory effect covered with a platinum coil to improve the visibility under fluoroscopy. It is inserted through a braided microcatheter to a position distal to the thrombus. After release from the microcatheter, it assumes a shape similar to a cork screw and has to be slowly pulled back under continuous aspiration via a balloon guiding catheter. More than 10,000 patients have been treated with this device. Currently the third-generation devices (V series) are used. With a 4.3F distal access catheter (DAC) an additional coaxial support can be added to the system, resulting in improved deliverability with the potential for simultaneous thrombo aspiration or IA thrombolysis. The Merci embolectomy system has been studied in the MERCI and Multi MERCI trials, where a recanalization up to 55% of treatable vessels was reported, and in 68% after adjunctive therapy (IA rtPA, mechanical). Clinically significant procedural complications occurred in 5.5% and ICH in 9.8% of patients (Bose A. 2008, Smith W. S. 2008). As an example how clot-retrievers are supposed to work the Merci retriever is shown in Figure 4.3.

The Phenox Clot Retriever (Phenox, Bochum, Germany) has been CE marked for the treatment of acute stroke in Europe since. It consists of a highly flexible nitinol/platinum-alloy compound core wire surrounded by a palisade of perpendicularly oriented stiff polyamide microfilaments trimmed in a conical shape. It is introduced into the target vessel through a microcatheter deployed distal to the thrombus and slowly pulled back under continuous aspiration via the guiding catheter. The smallest version of the device is used to recanalize distal MCA branches. Recently the second generation of the device (Phenox Clot Retriever CAGE), which incorporates a nitinol cage into the previous design, was constructed for the treatment of thrombi with firmer consistency. Recanalization was achieved in 56.3% of 45 patients with stroke with no device-related morbidity and mortality (Henkes H. 2006). The Neuronet device (Abbot Vascular, Temecula, CA, USA) has also been used successfully to retrieve intracranial clots.

It is a microguidewire-based laser-cut nitinol basket open proximally with the crisscrossing basket portion tapering to a shapable platinum-tipped wire (Mayer T. E. 2002). Very similar is the Catch (Balt Extrusion, Montmorency, France) device, a derivative of a self-expanding braided nitinol stent.

Figure 4.3. *Endovascular Therapy for acute stroke*: The principle of clot retrieving. The Merci System. Endovascular therapy for acute stroke is always performed under general anesthesia. First the MerciBalloon Guide Catheter is placed in the common or internal carotid artery for anterior circulation occlusion. Using standard cerebral catheterization techniques, a microcatheter is guided then through the guide catheter into the occluded vessel and passed beyond the thrombus (a). The Merci Retriever is now advanced through the microcatheter, and several of the helical loops are deployed distal to the thrombus. The Merci Retriever is then retracted to the face of the thrombus, and the proximal loops are deployed within the thrombus (b). The balloon of the Merci Balloon Guide Catheter has to be inflated now to arrest orthograde blood flow during removal of the thrombus. At least the Merci Retriever with the ensnared thrombus and the microcatheter are withdrawn together into the balloon guide catheter lumen. Continuous aspiration is applied to the guide catheter to promote complete evacuation of the thrombus (c). Once a retrieval attempt is completed, the balloon of the balloon guide catheter is deflated to re-establish flow. If the clot could not be removed with the retriever, the procedure can be repeated up to 5 times.

It is a nitinol basket, closed at its distal end and anchored with a pair of nitinol wires for insertion and withdrawal at the proximal end (Chapot R. 2005).

A comparison between the Merci and the Catch devices in an animal model has demonstrated superiority of the Merci retriever, which resulted in higher rates of overall

recanalization (90% versus 70%), higher chances of recanalization at the first attempt, and a lower rate of thrombus fragmentation/distal embolization (Breckenfield C. 2008).

The Alligator Retrieval Device (Chestnut Medical Technologies, Menlo Park, CA, USA) is a retriever with 4 small grasping jaws attached to the tip of a flexible wire. This device has been used to treat 6 patients with intracranial clots (predominantly MCA), resulting in rapid clot removal and clinical improvement in all patients. In limited experience it provided a rapid, safe, and effective means for achieving revascularization (Kerber C. W. 2007). The In-Time Retriever (Boston Scientific, Natick, MA, USA) has 4–6 wire loops and tends to bow when opened but has no specific opening to capture the embolus. This device has been successfully used in case studies (Bergui M. 2006). The performance of 5 different embolectomy systems was recently evaluated using an in vitro pulsatile flow model. The Merci, Catch, and Phenox retrievers were equally able to mobilize and remove most thrombi, whereas the In-Time and Attractor devices achieved only partial thrombus removal at best, and with considerable difficulty during initial thrombus penetration and placement of the device (Liebig T 2008).

AUGMENTED FIBRINOLYSIS

The MicroLysUS infusion catheter (EKOS, Bothell, WA, USA) is a microcatheter with a piezoelectric element at its distal tip, which creates a microenvironment of ultrasonic vibration to facilitate thrombolysis. This is achieved by a combination of a noncavitating sonography, which reversibly separates fibrin strands, and acoustic streaming, which increases fluid permeation, resulting in increased drug-thrombus surface interaction. In a pilot study 14 patients were treated with IA rtPA or reteplase infusion through the EKOS microcatheter and simultaneous sonography transmission for 60 min. Recanalization was achieved in 57% of patients and good clinical outcome in 43%. The mortality rate was 36%. A comparison of angiographic outcomes between subjects treated in the IMS-II trial with the EKOS catheter and IMS-I subjects treated with the standard microcatheter demonstrated recanalization in 73% versus 56% respectively. This device is being investigated further in the IMS-III trial (Nogueira R. G. 2008).

THROMBUS ENTRAPMENT

Stent placement of an acutely occluded intracranial vessel may provide fast recanalization by entrapping the thrombus between the stent and the vessel wall. This may be followed by thrombus dissolution via either endogenous or pharmacologic thrombolysis (Nogueira R. G. 2008). Treatment with balloon-expandable stents showed a recanalization rate of 79% and no symptomatic ICHs (Levi E. I. 2006). Multiple intracranial self-expandable stents are used in acute stroke therapy, although primarily designed for the treatment of wide neck aneurysms: the Neuroform (Boston Scientific), the Enterprise (Cordis, Miami Lakes, FL, USA), the LEO (Balt Extrusion, Montmorency, France) and the Solitaire/Solo stent (ev3 Endovascular, Plymouth, MN, USA). The Wingspan stent (Boston Scientific) is approved for the treatment of intracranial atherosclerotic lesions. Using these stents during stroke

treatment, Gp IIb/IIIa inhibitors are administered intra- or immediately post procedurally to avoid acute in-stent thrombosis. Isolated case reports of successful intracranial recanalization with these stents have been reported (Fitzesimmonis B. F. 2006). The Pharos Vitesse stent (Micrus Endovascular), the only balloon-expandable stent approved for intracranial use, was used successfully in 4 patients with acute strokes (Killer M. et al. unpublished). The prospective 'First Food and Drug Administration-Approved Prospective Trial of Primary Intracranial Stenting for Acute Stroke' trial, called SARIS (Stent-Assisted Recanalization in Acute Ischemic Stroke) suggested primary intracranial stenting for acute stroke may be a valuable addition to the stroke treatment armamentarium (Levi E. I. 2009).

TEMPORARY ENDOVASCULAR BYPASS

The need for an aggressive antithrombotic therapy after stent implantation remains one of the major limitations to its use in acute stroke. However, the advent of closed-cell stents has allowed resheathing and removal of the stent after recanalization. The need for post-treatment dual antiplatelet therapy, which could potentially increase the risk of hemorrhagic conversion of the infarct, is not necessary. Recently the preliminary data about the use of the Solitaire/SOLO device as a temporary endovascular bypass and clot retriever were presented (Liebig T. et al. unpublished). A clinical case in which partial deployment of an Enterprise stent resulted in immediate recanalization of an occluded MCA that was refractory to IV and IA rtPA, IA abciximab, and mechanical manipulation, confirmed this therapeutic concept (Hussain M. S. 2010). The currently newest available device is the TrevoTM System (Concentric Medical, Mountain View, CA, USA), an innovative, easy-to-use thrombus retrieval system. The main component of the Trevo System is a stentrieverTM, a new generation of retrieval devices which is able to restore flow in the occluded brain territory and remove the clot under aspiration with the guiding catheter. The first 24 cases, recently been performed in Europe, showed promising results (Liebig T. et al. unpublished). The alternative reperfusion strategies use the collateral vasculature of the brain as well as retrograde and reversed flow. Retrograde reperfusion and flow reversal are experimental treatment techniques that cause total reversal of the cerebral circulation and perfusion of the venous system with arterial blood into the capillary bed, which is then physiologically proximal to the occluded artery.

FLOW AUGMENTATION

Global reperfusion or flow augmentation tries to increase cerebral blood flow (CBF) to perfuse the brain tissue distal to the occlusive thrombus via leptomeningeal collaterals. This retrograde reperfusion strategy may potentially lead to better recanalization rates when used as an adjunct to antegrade reperfusion treatments. The increase in CBF should result in the better delivery of thrombolytic drugs to the occlusion site, theoretically leading to better recanalization with systemic thrombolysis. Flow augmentation can be achieved mechanically with the NeuroFlo device (CoAxia, Maple Grove, MN, USA). The NeuroFlo device is a dual balloon catheter designed for partial occlusion of the aorta above and below the origin of the

renal arteries. It is intended to increase blood flow to the brain and thus potentially reduce the damage caused by stroke. The recently completed SENTIS Phase III trial (Safety and Efficacy of NeuroFlo Technology in Ischemic Stroke) assesses the safety and efficacy of the NeuroFlo™ catheter for use in patients with ischemic stroke. The results are not yet published. Another ongoing ‘Study to Evaluate the Effects of the Neuroflo Device in People Who Have Had a Stroke’ investigates the feasibility and safety of the NeuroFlo™ in patients with persistent arterial occlusion after attempted thrombectomy with the Merci1 Retriever System. Delayed symptomatic reocclusion after initial endovascular stroke therapy can lead to sudden clinical deterioration and has been linked to poor clinical outcomes (Hussain M. S. 2010). The rate of reocclusion after endovascular treatments is 18% (Janjua N. 2008). This may be underestimated as many patients present with large clinical deficits at time of presentation and explain the low rate of good clinical outcome despite of a high rate of revascularization.

REPERFUSION THERAPIES

The advantages of pharmacological thrombolysis over mechanical means are: The drugs are easier to administer and – ‘Time is Brain’: they can be started faster. Future newer generation lytics and platelet inhibitors may be even faster, effective and specific. The disadvantages are that often no success can be achieved, and although the therapy can be initiated quickly, the effect occurs slowly and the risk of local and systemic hemorrhagic complications is evident. The major disadvantages of an invasive procedure are additional risks and high costs compared with IV rtPA that are weighted against achieving higher reperfusion rates. The current approach to acute endovascular stroke therapy is the use of mechanical clot-retrievers in combination with pharmacological agents. Future trials will address that and explore combined treatment strategies with neuroprotectants, antithrombotics, and supplementary mechanical strategies.

THROMBOLYTIC AGENTS

The critical time period during which this volume of brain tissue is at risk is referred to as the “window of opportunity”. At present, intravenous administration of tissue plasminogen activator (t-PA) within 3 h of symptom onset is the only US FDA-approved treatment available to re-establish cerebral blood flow. Early reperfusion with t-PA increases recovery from stroke symptoms by ~30%, with a low rate of serious complications. This will not only rescue neuronal and glial cells within the penumbra, but also glial cells from the central ischemic core zone, thereby limiting the size of infarcted tissue (Turner R. 2007). However, despite the beneficial outcome of early reperfusion, only 3%–8.5% of eligible stroke patients receive t-PA because of the possibility of intracranial hemorrhage (Bambour K. Z. 2006). The American Heart Association recently suggested that selected patients may benefit from t-PA up to 4.5 h after stroke, but some counter that the risk of hemorrhagic complications beyond 3 h following ischemia is significantly greater due to breakdown of the BBB (Sue E. J. 2008). In addition, the increase in cerebrovascular permeability results in diffusion of t-PA to the

brain parenchyma (Yepes M. 2003), causing neurotoxicity (Gotto H. 2007). To extend treatment availability to patients with stroke and to reduce the potential for intracranial hemorrhage, intraarterial thrombolysis is a viable option for those who present for medical treatment in the 3–6 hour time window (Zaidat O. O. 2002). The strategy behind intraarterial administration is rapid local delivery of a thrombolytic agent through a microcatheter placed near the site of occlusion. This leads to improved recanalization and reduced hemorrhagic complications due to lower doses of thrombolytic agent required to resume blood flow (Rha J. H. 2007). The disadvantages include the relative complexity of the procedure, delays in initiation of treatment, required technical expertise, and the invasiveness of the procedure (Nogueira R. G. 2009). To address the above issues, particularly to compensate for the delay in receiving the treatment, a combination therapy of intravenous and intraarterial thrombolysis has been tested. The initial partial recanalization with intravenous injection of t-PA is followed by complete recanalization via direct intraarterial delivery (Lawendowski C. A. 1997).

PROMISING DIRECTIONS AND POTENTIAL TARGETS IN NEUROPROTECTANT DEVELOPMENT

Despite past shortcomings in neuroprotectant development, multiple pharmacologic agents are currently under investigation in advanced phases of clinical trial development and appear promising based on early phase results. This includes Arundic Acid (ONO-2506), an astrocyte modulator, and minocycline, an inhibitor of microglia.

MODULATING ASTROCYTE ACTIVITY

While neuroprotection research has been largely neurocentric in nature and failed to emphasize the prominent role of glia in both homeostasis and injury response, the suggestion has been made that preservation of neuronal survival and function may not be possible without significant regulation of the microenvironment by astrocytes. Astrocytes, frequently described as “housekeeping cells of the nervous system”, are involved in regulating blood-brain barrier (BBB) integrity, removal of metabolic waste products, release of neural growth factors, and uptake of excess neurotransmitter release during synaptic activity. As such, astrocyte modulation represents a promising strategy for future therapeutic development for ischemic stroke (Takano T. 2009). The effect of ischemia on astrocytes is widespread in that signaling amongst astrocytes, as well as between astrocytes and neurons or microglial cells, is likely altered in addition to the potential for necrotic or apoptotic cellular death. This disrupted signaling likely has significant consequences on the control of basic physiologic functions including cerebral blood flow, glutamate uptake by astrocytes, and the ability of astrocytes to serve as an energy reserve during ischemia (Bambrick L. 2004, Carmignoto G. 2010, Rosi D. J. 2007, Zonta M. 2003). Perhaps the hallmark event involving astrocytes following neural injury, and specifically ischemia, is the development of reactive gliosis and associated morphologic changes and altered gene expression. One of the challenges in modulating astrocyte activity, and associated gliosis, for therapeutic benefit is the emerging

evidence that astrocytes have both protective and detrimental roles, potentially a result of multiple astrocyte subtypes (Zamanian J. L. 2012). Recent work by Zamanian, *et al.* have illustrated this concept in that ischemia appears to promote a protective astrocytic response whereas neuroinflammation induced by lipopolysaccharide (LPS) produces a potentially detrimental phenotype.

Notably, these two different stimuli each induced significantly altered gene expression yet the expression shared between stimuli was less than 50%, furthering the notion of a stimulus-specific astrocyte response or multiple astrocyte subtypes (Zamanian J. L. 2012). The influence of astrocytes on outcome following neurologic injury, and the potential for conflicting roles (beneficial or detrimental), has been seen clearly in a variety of preclinical models including ischemia, experimental autoimmune encephalitis (EAE), and spinal cord injury to name a few. In a preclinical model of ischemia, Li and colleagues demonstrated a protective role of astrocytes by knocking out glial fibrillary acidic protein (GFAP) and vimentin.

Deletion of this combination of intermediate filaments, characteristic of astrocytes, resulted in infarct volumes two to three times larger than in wild-type animals (Li L. 2008). In spinal cord injury, a dual role of astrocyte reactivity has been observed in which initially, astrocytes appear to modulate inflammation and contain inflammatory cells to the damaged region.

On the other hand, astrocytes are the primary component of the glial scar that prevents axonal re-growth in the chronic period post-injury (Okada S. 2006). In a model of demyelinating disease, experimental autoimmune encephalitis (EAE), targeted genetic removal of reactive astrocytes resulted in diminished perivascular scar formation and increased leukocyte infiltration into brain parenchyma. The exacerbated inflammatory response was associated with a detrimental outcome (Voskuhl R. R. 2009).

Despite the expanded understanding of astrocyte roles in homeostasis and disease, clear knowledge gaps remain. This includes more clear elucidation of the timing of beneficial versus detrimental responses to injury, how these responses can be pharmacologically manipulated, and how the astrocyte response is altered in association with disease comorbidities and the aging process. Our laboratory and others have begun to explore these factors with the hope of improving the understanding of neural injury in order to develop future therapeutics (Cotrino M. L. 2002, Dinapoli V. A. 2010). One potentially promising therapeutic that alters astrocyte activation, and synthesis of S-100B, that has advanced to clinical trials is (*R*)-(-)-2-propyloctanoic acid (ONO-2506). S-100B is expressed by reactive astrocytes throughout the penumbral region following ischemia and leads to nitric oxide release from the astrocyte, potentiating neuronal cell death (Teteshi N. 2002). In an early phase clinical trial, ONO-2506, also known as arundic acid, proved safe and produced a trend towards functional improvement based on the National Institutes of Health Stroke Scale (NIHSS) (Pettigrew L. C. 2006).

INHIBITING EFFECTS OF MICROGLIA

Much like astrocytes, microglial modulation may represent a promising therapeutic target for ischemic stroke based on the progression of compounds such as minocycline in clinical trials.

Microglial activation, a hallmark of the inflammatory response within the central nervous system post-stroke, has been described as both beneficial and detrimental in nature (Yenari M. A. 2010). Ablation of Mac-2 positive microglia, a marker of activated microglia, resulted in enhanced infarct volume and altered temporality of pro-inflammatory cytokine release. These changes were associated with a nearly three-fold increase in apoptotic cells and a nearly two-fold decrease in IGF-1, a neurotrophic factor, levels (Lalancetti-Hebert M. 2007). In contrast, numerous other studies have shown an improvement in outcome following ischemia by reducing microglial activation (Hayakawa K. 2008, Sakata H. 2012). This is achieved by administration of minocycline, traditionally used as an antibiotic, which has been associated with diminished Iba-1 expression, an activation marker, by microglia (Hayakawa K. 2008). Importantly, the microglial response post-stroke begins rapidly but takes hours to days to develop fully, potentially resulting in an extended window of therapeutic opportunity (Yenari M. A. 2010). The idea of an extended window, at least in comparison to that used for thrombolytic therapy, is consistent with preclinical findings in which a clinically relevant dosage of minocycline decreased infarct volume at both 4 and 5 h post-stroke while reducing functional deficits with 4 h administration (Xu L. 2004). In addition to the effects on microglia, minocycline has been shown to alter the function of other immune cells previously implicated in ischemic damage such as macrophages (Campbell J. H. 2011). While not previously investigated specifically with regards to ischemia, the effect of minocycline on macrophages may be related to alterations in macrophage recruitment and/or macrophage polarization, a topic that is discussed at greater length in subsequent sections. The effect of minocycline on subsequent inflammatory processes is logical in that microgliosis following injury is associated with not only the acute and rapid activation of microglial cells but also the recruitment of marrow-derived inflammatory cells that migrate to the brain and penetrate the parenchyma (Lalancetti-Hebert, M. 2007). The precise mechanism via which minocycline mediates protection through microglial-mediated effects remains unclear but has been shown to decrease expression of high-mobility group protein B1 (HMGB1) and *in vitro*, reduces oxidative stress via diminished superoxide release (Hayakawa K. 2008, Yenari M. A. 2006). Minocycline may also prove beneficial in other reparative therapies post-stroke, such as stem-cell delivery. Sakata and colleagues demonstrated that minocycline pre-conditioning of neural stem cells prior to transplantation resulted in production of beneficial paracrine factors and diminished graft cell death via upregulation of antioxidant genes associated with Nrf2 (Sakata H. 2012). In early phase clinical trials, minocycline has exhibited similar promise in that it has been proven safe when administered alone or in combination with thrombolytics and also exhibited potential efficacy in these small studies. Namely, NIHSS and modified Rankin Scale (mRS) scores were lower, and Barthel Index (BI) scores higher, in the group given minocycline. This improvement was seen as soon as 7 days post-stroke and persisted at day 30 of follow-up (Lampl Y. 2007). While a large efficacy trial is needed to confirm preliminary findings, minocycline appears promising for the treatment of ischemic stroke (Fagan S. C. 2011). Notably, clinical studies have also shown that minocycline administration results in diminished levels of matrix metalloproteinase-9 (MMP-9) (Switzer J. A. 2011). Preclinical studies have shown a reduction in blood-brain barrier (BBB) permeability following minocycline administration and due to previous associations between BBB permeability and MMP-9 activity, it would appear that these clinical findings indicate a potential effect of minocycline on restoration or maintenance of BBB integrity (Yenari MA 2006, Switzer JA 2011).

NEUROPROTECTIVE THERAPIES

Thrombolysis is likely an effective therapeutic modality because it helps restore blood flow and improve cellular metabolism in ischemic regions not yet irreversibly injured. However, thrombolysis is not targeted at the cellular consequences of ischemia. Therefore, it is essential to add a component that would act as a neuroprotective or prevent the damage caused by reperfusion injury. In fact, the Stroke Progress Review Group, which is charged with assisting the National Institute of Neurological Disorders and Stroke (NINDS) in addressing the Institute's Stroke Research Program, has recommended research on combinations of neuroprotectants or neuroprotectants plus reperfusion therapy. Addition of neuroprotectants would protect neurons, which are susceptible to apoptosis, and could minimize the damage due to reperfusion injury.

MODULATING THE BLOOD-BRAIN BARRIER (BBB)

As focus has gradually shifted from solely the neuron to include glial cells and the associated neurovascular unit, the role of the blood-brain barrier in ischemic injury has received renewed interest. Much of the work involving BBB permeability has focused on potential mechanisms of degradation, such as matrix metalloproteinases, creating a natural target for pharmacologic agents (Lee S. R. 2004a, Lee S. R. 2004b, Lo E. H. 2002, Rossel A. 2008, Zhao B. Q. 2006). In work by Pfefferkorn and colleagues, the authors showed the ability to reduce BBB disruption and improve survival following delayed tPA administration by using BB-94, a matrix metalloproteinase inhibitor (Pfefferkorn, T. 2003). In more recent work using a model of traumatic brain injury, a similar phenomenon was shown using Kollidon VA64, a pharmacological agent described as resealing membranes. Improving membrane integrity resulted in diminished neural injury and improved functional outcome (Mbye L. H. 2012). It is clear that more investigation is required to understand not only the role of BBB permeability in disease but also how to target BBB permeability therapeutically, but studies such as those described herein provide a potential proof-of-concept and perhaps most importantly, further indicate the need for a comprehensive approach to ischemic stroke therapeutic development.

TARGETING INFLAMMATION

As demonstrated by the early phase success of agents currently under investigation, such as minocycline and arundic acid, targeting inflammation may offer promise in the quest for identification of neuroprotective compounds. Inflammation offers many opportunities and targets for modulation, many of which persist for hours to days, sometimes even longer, following injury. Consequently, these targeted therapeutics are more likely to be administered within the window of opportunity for a given pathologic process compared to some of the previously tested agents that target events occurring almost immediately post-stroke. Inflammation, while generally thought of in a negative connotation, is an essential component of recovery and repair-associated processes as well, further complicating experimental

investigations. In this work, we focus on the dual responses associated with inflammation, particularly with regards to macrophage polarization, an emerging topic in both the inflammation and neuroscience literature.

INFLAMMATION: A DELETERIOUS EVENT OR A BENEFICIAL RESPONSE?

The inflammatory process is further complicated due to the fact that various elements can serve a deleterious or a beneficial role in the injury and recovery process, as highlighted earlier in this work with discussion of astrocytes and microglia. Another prime example of this potentially dual response to neural injury is that of macrophages. Macrophages and microglia may contribute to secondary injury processes via production of inflammatory cytokines and reactive oxygen species while also potentially reducing injury through maintenance of the cellular microenvironment by phagocytic clearance of cellular debris and apoptotic cells (David S. 2011, Popovich P. G. 2008). Emerging evidence indicates that many of these inflammatory cell types may never truly exist in a resting state and rather may almost constantly be undergoing changes in state through intermediary forms, evident by both morphologic and functional changes, in response to the cellular environment and signals from the surrounding regions (Pollazi E. 2010). This is perhaps most adequately described, and potentially targeted therapeutically, by macrophages. In the following section, we attempt to highlight some of the recent developments in the macrophage literature, particularly those related to various macrophage subsets and neural injury.

INFLAMMATION

Several inflammatory mediators such as leukocytes, adhesion molecules, acute phase reactants, cytokines and proteases increase in the plasma of patients with cerebral ischemia. The early central inflammatory events include the production of reactive oxygen species (nitric oxide, superoxide) expression of proteolytic enzymes (MMP-9, MMP-2), vasoactive substances (prostaglandins and cyclooxygenases) and vascular adhesion molecules (ICAM-1, P-selectin, L-selectin). Neutrophils and macrophages are considered early contributors to the production of ROS and cytokines, while activation of microglia and proliferation of astrocytes in the ischemic area further promotes the inflammatory response in later stages (Dennis A. 2009). Inflammatory mediators, [such as IL-1 β , IL-6, TNF α , IL-10, transforming growth factor beta (TGF β) and chemokines including MCP-1, macrophage inflammatory protein-1 (MIP-1), keratinocyte-derived chemokine/chemokine (CXC motif) ligand 1/(KC/CXCL1) and fractalkine (CX3CL1)], are also found in increased levels in brain tissue in animal models of stroke.

The expression of IL-1 β mRNA is increased in the ischemic rat brain within hours after the induction of stroke (Liu T. 1993), elevated levels of IL-6 are seen in the plasma and cerebrospinal fluid (CSF) 3–6 h after experimental stroke in mice (Clark W. M. 1999), and levels of pro-inflammatory cytokines such as IL-6, IFN γ , MCP-1 become elevated in the plasma within 6 hours in rodents (Offner H. 2006).

The intercellular adhesion molecule-1 (ICAM-1) antibody, Enlimomab, can reduce the size of stroke when given within 1 hr reperfusion after transient, but not permanent ischemia, in a rat stroke model.

However, its use was associated with significant worsening in the modified Rankin scale and higher mortality at 90 days compared to placebo in a large clinical trial (Enlimomab Group 2001). Blocking neutrophil activation by a recombinant protein inhibitor of the CD11b/CD18 receptor, UK 279,276 (Rovelizumab), within 6 hrs of stroke also failed to show any benefits in one clinical trial which was stopped prematurely. Despite promising results for interleukin (IL)-1 receptor antagonist (RA) in several animal studies, this drug has not been investigated in humans (Banwell V. 2009). FK506 also demonstrates benefits, particularly after transient ischemia, in animal studies and remains a potential target for studies in humans (Mecleod M. R. 2005).

Systemic administration of minocycline is protective in experimental models of focal (Yrjanheikki J. 1998) or global (Yrjanheikki J. 1999) cerebral ischemia. Inhibition of IL-1 β converting enzyme (Harra H. 2007) or deletion of IL-1 β and IL-1 α results in markedly reduced ischemic damage and neuronal death in animal studies (Boutin H. 2001). Deficiency of inflammatory chemokines such as MCP-1 (Huges P. M. 2002) or fractalkine (Soriano S. G. 2002) is associated with less vulnerability to ischemic injury.

Cerebral ischemia activates an inflammatory reaction within hours of the injury. The suppression of inflammation using a variety of drugs has been shown to reduce infarct area in animal studies. Commonly used anti-inflammatory agents are aspirin and the lipid lowering statins.

A combination of aspirin and extended release dipyridamole was found to be more efficacious than aspirin alone for nonfatal stroke by the second European Stroke Prevention Study (ESPS-2) and the European/Australian Stroke Prevention in Reversible Ischemia Trial (ESPRIT) (Deb P. 2007).

In an investigation of the anti-inflammatory and neuroprotective properties of statins, the Stroke Prevention by Aggressive Reduction in Cholesterol Level study showed that treatment with high-dose atorvastatin reduces the risk of stroke in patients with the first attack of stroke and no known coronary artery disease (Gedikli O. 2008). In addition to aspirin and statins, two leukocyte adhesion inhibitors, Enlimomab and LeukArrest, were studied in patients with ischemic stroke. Although Enlimomab was shown to reduce the damage in stroke models, patients who received it experienced significantly more negative effects relative to placebo controls (Cheng Y. D. 2004).

Another neuroprotective approach was explored in the “Intravenous Thrombolysis Plus Hypothermia for Acute Treatment of Ischemic Stroke (ICTuS-L)” study of the effects of induced hypothermia and thrombolysis after acute ischemic stroke. Hypothermia is thought to serve a neuroprotective role in stroke via inhibition of the MIP-3 α -CCR6 inflammatory pathway (Shintani Y. 2011).

Although hypothermia has been shown to confer some protection against damage in cardiac arrest and neonatal hypoxic-ischemic encephalopathy patients (Lundby J. B. 2011, Jacobs S. E. 2011), its effectiveness in acute ischemic stroke has not been definitively demonstrated. Negative consequences, including pneumonia, were seen more frequently in patients who had undergone hypothermia treatment, compared to controls in this study. Disappointingly, there was no significant benefit in mRS between the two trial groups (Hemmen T. M. 2010).

EXCITOTOXICITY AND NMDA GLUTAMATE RECEPTORS

Excessive NMDA (N-methyl D-aspartate) receptor activation has been implicated in the pathophysiology of several neurodegenerative diseases and in stroke. Excitotoxicity has been a widely investigated area in stroke. Ischemic neuronal injury in vitro is dependent on synaptic release of excitatory amino acids and resultant elevation of intracellular free calcium. Even transient exposure to excess excitatory amino acids (EAAs) is toxic to cultured neurons, and alterations in neuronal energy balance increases the vulnerability of neurons to excitotoxic damage even in the presence of physiological concentrations of EAAs (Muir K. W. 1995). Evidence that this process progresses over several hours after the ischemic insult highlights a potential role for neuroprotective strategies administered during the critical window prior to irreversible loss, although the exact duration of this window in humans remains unknown. The action of glutamate on NMDA receptors seems to play an important role in glutamate-mediated toxicity. Compounds that decrease glutamate levels or interfere with its binding to this receptor have been the focus of many studies in this area (Nagai Y. 2008). NMDA antagonists, which have been investigated in stroke include Aptiganel hydrochloride (CNS 1102, Cerestat), dextrorphan and dextromethorphan. Their use was associated with side effects and no clear clinical benefit in clinical trials (Muir K. W. 1995). Phase 2 trials of both oral and IV forms of remacemide hydrochloride in stroke are currently underway. Magnesium ion, which electrophysiologically behaves as a noncompetitive NMDA antagonist, has demonstrated efficacy as a neuroprotective agent in focal and global models of cerebral ischemia. Two preliminary trials of IV magnesium show no evidence of adverse effects (Muir K. W. 1994, Wester P. 1985), and phase 3 trials are currently underway. A phase 2 trial of Selfotel (CGS 19755) in acute stroke patients, reported evidence of a dose-dependent toxicity (Clark W. 1994). Selective NMDA antagonists such as ifenprodil and eliprodil (SL82.0715) have demonstrated preclinical neuroprotective efficacy, and eliprodil is currently being investigated in early phase 3 trials in stroke patients. Other compounds under investigation are 3-(2-carboxypiperazin-4-yl)propyl-1-phosphonic acid (CPP), its derivative d-CPPene, and CGS 19755 (Taylor C. P. 1994). Neuroprotection is evident for the presynaptic glutamate release inhibitors 619C89 and ubeluzole when administered within 6 hours of induced ischemia. Both drugs are currently in phase 2 trials in stroke. Partial glycine agonists, such as HA 966, L687414, and 1-aminocyclopropanecarboxylic acid (ACPC), or full antagonists, such as 7-chlorokynurenic acid and its derivatives or ACEA 1021, are effective in stroke models. Glutamate antagonists at other receptor subtypes, such as the AMPA receptors, are under evaluation (Muir K. W. 1995).

MITOCHONDRIAL DYSFUNCTION

The release of multiple apoptogenic proteins from mitochondria has been identified in ischemic and post-ischemic neurons. Results from animal models strongly implicate caspase-dependent and caspase-independent apoptosis and the mitochondrial permeability transition as important contributors to tissue damage, particularly when induced by short periods of temporary focal ischemia (Sims N. R. 2009). Prophylactic administration of oral creatine reduces the size of ischemic brain infarctions in mice. The anti-oxidant Szeto-Schiller peptide

(SS-31) plays an important role in modulating ROS-induced mitochondrial permeability transition and cell death, and has been found to be protective in several *in vitro* and *in vivo* models of ischemia and reperfusion injury. Synthetic triterpenoids (TP) are analogues of oleanolic acid, which exert anti-oxidative effects through stimulation of the antioxidant response element (ARE)–Nrf2–Keap1 signaling pathway, and have been shown to be protective in a rat model of cerebral ischemia (Chatturvedi R. K. 2008).

ANTI-APOPTOTIC AGENTS

Caspase is a group of cysteine proteases that induce apoptotic cascade when activated. Inhibition of caspase activity has been shown to reduce the size of infarction in rodent stroke models (Cheng Y. 1998, Endres M. 1998). However, none of the caspase inhibitors have yet been tested in clinical trials. A 2009 study on the efficacy of erythropoietin as a neuroprotectant yielded negative effects and safety concerns after it was shown that not only did erythropoietin not confer a neuroprotective benefit, but erythropoietin in combination with the current standard of care, rt-PA, increased the risk of death, intracerebral hemorrhage, brain edema, and thromboembolic events (Ehrenreich H. 2009). Thus, future studies should evaluate the effect of putative therapeutic agents in conjunction with the use of rt-PA where appropriate. These studies demonstrate some of the challenges faced in seeking neuroprotective agents to reduce the initial damage wrought by ischemic stroke.

In general, anti-apoptotic mechanisms being evaluated in neuroprotection include strategies to prevent caspase-dependent apoptosis (e.g., caspase inhibitors) or strategies to prevent caspase-independent apoptosis (e.g., PARP inhibitors). Both caspase-dependent and caspase-independent mechanisms of cell death are implicated in focal cerebral ischemia. Increased expression of Fas and of mediators of the extrinsic caspase-dependent pathway have been shown following focal ischemia. Increased expression of caspase-1, -3, -8, and -9, and of cleaved caspase-8, has been observed in the penumbra. The role for apoptosis in ischemia is further supported by reports that the inhibition of caspase-3 reduces infarct size after transient focal ischemia (Ferrer I. 2003). Intranuclear MMP activity facilitates oxidative injury in neurons during early ischemia through the cleavage of PARP-1 and XRCC1, and resultant disturbance of DNA repair mechanisms. Inhibition of MMP with the broad-spectrum inhibitor, BB1101, significantly attenuated ischemia-induced PARP-1 cleavage, and resultant cell death in rat model of focal cerebral ischemia (Yang Y. 2009). The p53-dependent receptor pathway also seems to be involved in stroke induced apoptosis. Injection of netrin-1, a ligand of the receptor uncoordinated gene 5H2 (UNC5H2), was associated with significantly reduced infarct volume at 3 days after focal ischemia in an animal model of stroke, through its inhibition of p53-mediated apoptosis (Wu T. W. 2008). Estrogen has also been shown to prevent Fas-mediated apoptosis in experimental models of stroke (Jia J. 2009).

ANTIOXIDANT THERAPY

Excessive production of reactive oxygen species (ROS) after cerebral ischemia and reperfusion is implicated in brain damage through different cellular and molecular

mechanisms, and it is further aggravated by impaired cellular antioxidant defense systems under ischemic conditions. Upon reperfusion, cells are often in a state of oxidative stress, which results in further tissue injury, known as reperfusion injury (Adibhatla 2008a and 2008b). ROS are usually scavenged by antioxidant enzymes, primarily superoxide dismutase (SOD), by catalyzing the dismutation reaction of the superoxide anion to hydrogen peroxide (H_2O_2).

Catalase and glutathione peroxidase, on the other hand, protect cells from the toxic effects of H_2O_2 by catalyzing its decomposition into water (Margail I. 2005). However, two pharmacodynamic factors impede the straightforward use of native forms of antioxidant enzymes in cerebral ischemia. First, their molecular weight is well below the renal glomerular filtration cutoff, resulting in their rapid clearance from systemic circulation (e.g., $t_{1/2}$ of SOD in rats = 4–8 min, catalase = 8–10 min). Second, they are negatively charged at physiologic pH and therefore do not readily cross cell membranes (Francis J. W. 1997). Transient disruption of BBB permeability might permit some access of exogenous enzymes to ischemic neuronal tissue, but they do not permeate cells; neurons and astrocytes do not appear to take up the native enzyme under normal conditions, and hence cannot neutralize ROS formed intracellularly (Schaller B. 2004). Because of these challenges, animal studies have shown no improvement in cerebral blood flow or neurological recovery with SOD or SOD with catalase (Forsmann M. 1998, Schurer L. 1990).

Different alternatives have been investigated to address these issues: for instance, PEGylation and lecithinization to improve the circulation half-life (Tsubokawa T. 2007) and fusion of enzymes, e.g., SOD, with cell membrane-penetrating peptides like transactivator of transcription (TAT) of human immunodeficiency virus or tetanus toxin fragment to increase its ability to cross the BBB (Kim D. W. 2005). However, there are limitations to these modifications. For example, PEGylated SOD (PEG-SOD) increases the enzyme's stability in circulation from 6 min to 36 h, but it limits the permeability of SOD across cerebral cell membranes and its ability to be taken up by neuronal cells (Veronesse F. M. 2002). Similarly, fusion of different cell-penetrating or cell-specific peptides to target proteins requires a crosslinker via a chemical process that could cause denaturation and loss of activity of the target protein (Morris M. C. 2001).

There is also a concern regarding the possible immune-mediated anaphylactic responses to hybrid proteins given to patients (Francis J. W. 1997). Intravenous delivery of SOD loaded into liposomes has shown partial inhibition of infarct volume, but the instability of liposomes *in vivo* (half-life ~4.2 h) limits the duration of SOD activity and efficacy (Imazumi S. 1990, Sinha J. 2008). Our approach uses biocompatible, biodegradable nanoparticles (NPs) loaded with superoxide dismutase (SOD-NPs) with the aim to reduce the damaging effect of ROS. These NPs are formulated using poly dl-lactide *co*-glycolide (PLGA) with antioxidant enzymes encapsulated. The enzyme encapsulated in NPs is released in active form. Our initial studies demonstrated the neuroprotective effect of SOD-NPs in oxidative stress-challenged human neural cells, whereas SOD in solution and PEG-SOD were ineffective. The mechanism of protective efficacy of SOD- NPs appears to be due to sustained bioavailability of antioxidants and intracellular delivery of antioxidant enzymes (Reddy M. K. 2008). In our first *in vivo* ischemic middle cerebral arterial occlusion rat stroke model (Reddy M. K. 2009), we determined that the most efficient method of delivery of NPs is via intracarotid artery injection. The study with dye-loaded NPs demonstrated NP localization primarily to the

cortex and striatal regions of the ischemic hemisphere, but not to the nonischemic hemisphere.

Our results demonstrated that over 75% of SOD-NP-treated animals showed increased survival and neurological recovery over a time period of 28 days. In addition, a reduction in breakdown of the blood-brain barrier in treatment animals was evidenced by significantly decreased Evans blue leakage in the brain. These results have driven further research into the neuroprotective effects of SOD-NPs, as well as investigation into how we can further abrogate the negative effects of ROS production in ischemic stroke.

The protective effect of SOD-NPs could be due to the direct antioxidant effect of the active enzyme released from the NPs localized in the brain. It is possible that SOD-NPs prevented the cascade of events or acted on several stages in the pathophysiology of reperfusion injury. Breakdown of the BBB is an early event arising from free-radical damage, especially from superoxide radicals generated in endothelial cells during ischemia and reperfusion (Rosenberg G. A. 2007). SOD-NPs localized in the lining of the cerebral vasculature protected the BBB from free-radical injury, which then could have prevented the leukocyte adhesion that otherwise is a common event following reperfusion as well as prevented edema formation (Kuroda S. 1997).

We are investigating further to understand the mechanism of recovery of animals with time. It is quite possible that the conducive conditions created in the brain as a result of the sustained free-radical scavenging effect of SOD released from NPs localized in the brain (Yasui K. 2006) could have played a role in facilitating the process of angiogenesis and neurogenesis in the infarcted brain. Recently, we began working on developing a thromboembolic rat stroke model to mimic the clinical scenario (Zhang Z. 1997). We are now testing how SOD-NPs and catalase-loaded NPs, or combination of these formulations, would perform in the presence of t-PA and whether we can extend the window of t-PA treatment with effective antioxidant delivery.

Therapeutic strategies based on exogenous delivery of the native form of superoxide dismutase (SOD), a free radical scavenger, are limited because of its short half-life (~6 min) *in vivo* and poor permeability across the blood-brain-barrier (BBB). We encapsulated SOD in biodegradable poly(D,L-lactide *co*-glycolide) nanoparticles (SOD-NPs) and tested their efficacy in a rat focal cerebral ischemia-reperfusion injury model. We hypothesized that localized brain delivery of SOD-NPs would sustain the protective effect of SOD by neutralizing the deleterious effects of ROS formed following ischemia-reperfusion. SOD-NPs were administered at the time of reperfusion *via* the intracarotid route to maximize their localization in the brain. Animals receiving SOD-NPs (10,000 U of SOD/kg) demonstrated a 65% reduction in infarct volume, whereas an equivalent dose of SOD in solution (SOD-Sol) increased it by 25% over saline control ($P < 0.001$; data at 6 h following reperfusion). Control NPs alone or mixed with SOD-Sol were ineffective in reducing infarct volume, with results similar to saline control, indicating the protective effect of the encapsulated enzyme. SOD-NPs maintained BBB integrity, thereby preventing edema, reduced the level of ROS formed following reperfusion, and protected neurons from undergoing apoptosis. Animals treated with SOD-NPs demonstrated greater survival than those with saline control (75% vs. 0% at 28 days) and later regained most vital neurological functions. SOD-NPs may be an effective treatment option in conjunction with a thrombolytic agent for stroke patients.—Reddy, M. K., Labhasetwar, V. Nanoparticle-mediated delivery of superoxide dismutase to the brain: an effective strategy to reduce ischemia-reperfusion injury.

GLUTAMATE ANTAGONISTS

Radical scavengers (such as vitamin E, sulfhydryl compounds and nitron spin traps), agents that promote detoxification of ROS (superoxide dismutase, catalase or peroxidase conjugates), and agents that prevent radical generation (e.g., the xanthine oxidase inhibitor allopurinol, nitric oxide synthase inhibitors, or nonsteroidal anti-inflammatory agents and cyclooxygenase-inhibitors) have been studied in stroke. The use of NXY-059 has been associated with clinical benefits in animal models of stroke, and was associated with a significant improvement in the modified Rankin functional scale in the Stroke-Acute Ischemic NXY Treatment-I (SAINT-I) (Lees K. R. 2006). However, these results were not reproduced in the expanded SAINT-II trial (Feuerstein G. Z. 2008, Shuaib A. 2007). Ebselen and the radical scavenger edaravone (MCI- 186, Radicut) were associated with clinical improvement in a small trials (Green A. R. 2005).

Glutamate antagonists are the most studied neuroprotective agents. As mentioned earlier, glutamate is one of the excitatory CNS neurotransmitters and is released excessively during ischemia (Guyot L. L. 2001). Several receptors relevant to neuroprotection, such as NMDA, AMPA, KA, and metabotropic receptors, are activated by glutamate. Since the activation of most of these receptors is associated with calcium influx leading to cell damage, both glutamate receptor antagonism and calcium channel blockers might serve a neuroprotective role. Although glutamate receptor antagonists have shown excellent neuroprotective effects in animal studies, these effects have not been validated in clinical studies. As a result, studies of several NMDA antagonists- Selfotel (CGS19755) (Boast C. A. 1988), Eliprodil (Gotti B. 1988) and Aptiganel (Cerestat, CNS 1102) (Aranowski J. 1994)- have been halted. Calcium channel blockers such as Nimodipine (Horn J. 2000) and Flunarizine also showed no significant benefit versus placebo in clinical trials. Despite these failures and various side effects at both the psychiatric and cardiovascular levels, the possibility of a role for glutamate receptor antagonists in neuroprotection still exists. A phase III trial with YM872, an AMPA receptor antagonist, is ongoing, and seeks to determine its potential efficacy in combination with *t*-PA thrombolysis. No clinical trials with metabotropic glutamate receptor antagonists have been conducted. It was recently reported that SP-8203, an NMDA antagonist, has dual effects that protect cells against excitotoxicity and improve memory in brain ischemic injuries (Noh S. J. 2011), suggesting a potential therapeutic role of SP-8203 in cerebral ischemic injuries. The main cause of failure of many approaches in clinical studies is inadequate dosing and timing of therapeutics, particularly an unrealistic time window derived from animal models that cannot be duplicated in humans (Leker R. R. 2002). The reasons for the failure of the most promising drug in a clinical study (NXY-059 in the SAINT II trial) are that the drug was not given to most patients within a 4- to 6-h time window as was used in animal studies and its inadequate drug levels in the brain (Feur Stein G. Z. 2008). One phase III trial, the FAST-MAG study, which aims to determine the safety of magnesium sulfate when administered acutely in the first minutes after stroke onset, addresses these issues by arming paramedics with tools to obtain consent and administer the experimental therapy within a hyperacute therapeutic window (Saver J. L. 2004). A pilot study for this trial found significantly improved modified Rankin scores (mRS) at day 90 for trial patients, and the study design has contributed a novel experimental strategy that could benefit other researchers in translating pre-clinical study results to field applications. Recognizing the

benefits of pre-hospital neuroprotective agent administration, the Stroke Treatment Academic Industry Roundtable (STAIR) meeting sets recommendations for priorities in stroke research, noting that the hyperacute treatment window could potentiate other interventions and increase the time window for other time-sensitive interventions (Albers G. W. 2011).

ION CHANNEL MODULATORS

As previously discussed, the influx of calcium, sodium and of potassium during the ischemic cascade leads to brain tissue damage (Ohta K. 2001). Therefore, ion channel modulators might have a neuroprotective role. Nimodipine, a calcium channel blocker that dilates intracranial blood vessels and improves the regional blood flow in the margins of the brain infarct, did not show any benefit in clinical trials. Similarly, Fosphenytoin, the sodium channel blocker, was shown to decrease the amplitude of sodium-dependent action potentials and to block voltage- dependent calcium entry into synaptosomes. Again, phase III clinical trials were terminated due to the lack of demonstrated benefit. The potassium channel activator Maxipost also failed at phase III clinical trials, even though it was expected to protect neurons by inducing neuronal hyperpolarization and decreasing the release of excitatory amino acids (Gribkoff V. K. 2001).

REPAIR AND RECOVERY STRATEGIES OF STROKE: TROPHIC FACTORS AND CELL-BASED THERAPIES

No matter how successful acute neuroprotective strategies become, many stroke patients may still fall outside of clinical time windows for effective treatment. Hence, approaches that promote repair and recovery will be essential for an integrated stroke armamentarium. Logically, these approaches can be divided into two categories—pharmacologic or trophic factor treatments that seek to amplify and augment endogenous processes of neurovascular plasticity and recovery and cell based therapies that seek to replace damaged or lost brain cells.

Many approaches that augment endogenous recovery have been explored. Growth factors such as NGF, FGF, GDNF, and BDNF have all met with variable degrees of success in animal models (Semkova and Kriegstein, 1999). But a limiting factor in many of these studies is their relatively large molecular weight, making transport into brain difficult. Some alternatives may yet exist, such as smaller peptides, transnasal delivery of growth factors to bypass the blood-brain barrier (Fletcher et al., 2009), peptidomimetics and compounds that can upregulate endogenous trophic factor production but do not require direct infusion into brain (Zhang and Chopp, 2009).

Additionally, one may also target inhibitory molecules that accumulate in the area surrounding the injury and block neuronal repair, such as chondroitin sulfate proteoglycans, myelin associated proteins, Nogo, and semaphorins (Silver and Miller, 2004). Although stroke-damaged brain usually exhibits varying degrees of spontaneous recovery, there will always be significant areas where endogenous repair is insufficient. In this regard, cell-based therapies may represent a new frontier. To date, a variety of cell sources have been tested,

including neural stem cells, bone-marrow-derived mesenchymal cells, as well endothelial progenitor cells (Koch et al., 2009). Treatments have typically involved direct transplantations into brain parenchyma, catheter infusions into cerebral ventricles, as well as systemic injections into circulating blood. The latter approach is especially intriguing, as complex mechanisms of cell targeting seem to be operational in brain. Infarcted brain tissue upregulates and releases various chemokines, such as SDF-1, to establish gradients that broadly serve to attract stem and precursor cell populations (Madri, 2009). Induced pluripotent stem cells may also provide an alternative cell source to embryonic stem cells (Takahashi and Yamanaka, 2006). One advantage is the theoretical possibility that cell repair can be custom designed to suit specific diseases or individual needs, as described in a flurry of recent studies showing that neurons can be successfully derived from pluripotent cells taken from patients with Huntington's disease, ALS, and spinal muscular atrophy (Dimos et al., 2008; Ebert et al., 2009; Park et al., 2008). Whether similar methods can be applied to stroke victims remains to be tested.

Overall, cell-based therapies in models of experimental stroke suggest that delayed repair is a viable treatment approach. But more work is needed to translate these promising results into effective stroke therapies. Many questions remain, and the precise mechanisms of cell-induced repair are still unclear. For example, do the reported benefits occur because cells are being explicitly replaced or because transplanted cells serve as a source of trophic factor production? How well do transplanted cells survive? Will adjunctive therapies to decrease apoptotic dropout be necessary? If cells survive, how well do they integrate into existing neural or vascular networks? What is the optimum timing for such therapy? What types of cells should be used?

And finally, what subtypes of stroke patients should be selected for robust clinical trial results? As the basic mechanisms of trophic and cell-based repair continue to be defined, an interesting underlying theme has emerged that links the survival of newborn or transplanted cells to the host environment. As discussed in the previous sections, activated vascular cells and microglia may be detrimental to cell survival in the early stages of cerebral ischemia, due to production of cytokines, ROS, and toxic amount of NO. In the recovery phase, however, chronically activated microglia may now secrete beneficial factors such as BDNF and GDNF. Hence, prolonged inflammation can serve biphasic roles—dampening cellular recovery acutely but then enhancing tissue repair later on.

In fact, this principle of biphasic mediators may be broadly applicable in stroke pathophysiology. There are many examples. Overactivation of NMDA receptors induces acute excitotoxicity (Besancon et al., 2008), but without NMDA signaling, chronic neuronal remodeling cannot take place (Young et al., 1999). Matrix metalloproteinases degrade and damage neurovascular substrates in the acute phase (Rosenberg, 2009), but the same proteases are critically important for neurovascular remodeling during the recovery phase (Zhao et al., 2006; Lee et al., 2006).

The intracellular mediator HMGB1 promotes necrosis and expands the core infarct during acute cerebral ischemia (Qiu et al., 2008), but during the repair phase, HMGB1 release from reactive astrocytes promotes angiogenesis and synaptic plasticity (Hayakawa et al., 2010a, 2010b). Altogether, the boundaries between cell death and cell repair may be blurred (Lo, 2008b). Future studies that dissect these biphasic mechanisms should prove fruitful if we are to develop clinically meaningful strategies for both neurovascular protection as well as repair.

MACROPHAGE POLARIZATION AS THERAPEUTIC TOOL

Macrophages have long been recognized as a key element in the inflammatory response, particularly in reference to the invasion of the body by foreign material such as bacteria. Besides their role as immune effector cells, macrophages are perhaps most important for normal homeostatic processes such as cellular turnover and clearance of cellular debris, hence the description of macrophages as the “janitorial” cell of the body. For example, macrophages are intimately involved in the clearance of over 200 billion erythrocytes each day as well as clearance of apoptotic cells. Consequently, macrophages respond to both endogenous stimuli produced through injury as well as to foreign cell types (Mosser D. M. 2008). As such, work in both the nervous system as well as other body systems indicates that macrophages can be shifted to either a pro-inflammatory or anti-inflammatory state depending on disease states and environmental cues. Gaining a better understanding of the processes mediating this phenotypic shift may lead to therapeutic advances (David S. 2011). Perhaps the greatest challenge in this process is the complexity of elucidating these mechanisms *in vivo*. *In vitro* studies allow for rapid stimulation of inflammatory cells with antigens or cytokines but this response often does not translate to *in vivo* work, or is at the very least, often modified in a significant way (Murray P. J. 2011).

M1 VERSUS M2: CLASSICAL VERSUS ALTERNATIVE ACTIVATION

Literature focusing on macrophage polarization and subtypes has followed a similar path to that of T-cell literature and, consequently, macrophages have largely been classified as M1 or M2, a description that persists despite evidence showing greater complexity, particularly amongst the M2 population (Figure 1) (Mosser D. M. 2011). In spite of the potential for additional subtypes, we use the conventional M1 and M2 descriptions for organizational purpose but do explore the potential for various M2 subtypes within this work.

CLASSICALLY ACTIVATED MACROPHAGES (M1)

Classical macrophage activation refers to those designated as effector cells as part of cell-mediated immune responses. In the past, classical activation occurred in response to two primary signals—interferon gamma (IFN γ) and tumor necrosis factor (TNF) (Mosser D. M. 2008). This results in increased secretion of pro-inflammatory cytokines and mediators such as IL-12, IL-23, IL-1 β , TNF- α , reactive oxygen species (ROS), and nitrosylated species (NS), ultimately producing increased microbicidal or tumoricidal capability (David S. 2011). While emerging evidence indicates that other signals may also induce an M1 response, such as certain toll-like receptor (TLR) agonists, the idea remains the same in that M1 macrophages, while vital for host defense, must be carefully regulated due to the possibility of host-tissue damage with unchecked activation. Persistent inflammation and the associated host-tissue damage is a hallmark of numerous autoimmune diseases such as rheumatoid arthritis and inflammatory bowel disease, demonstrating the need for regulation and strict control of activation processes (Mosser D. M. 2007).

Figure 4.4. *Macrophage polarization*: Classical M1 vs Alternative M2: Evolution of views of macrophage polarization from the more simplistic M1 or M2 characterization without subtypes to the alternative or developing view with the M2 population divided into “wound-healing” and “regulatory” subtypes. Even more current proposals identify three populations of M2-related macrophages involved in a range of functions.

ALTERNATIVELY ACTIVATED MACROPHAGES (M2)

Alternative macrophage activation, similar to classical macrophage activation, can occur in response to both innate and adaptive signals (Mosser D. M. 2007). The primary signaling molecule responsible for activation is interleukin-4 (IL-4), a cytokine released upon initial tissue injury as well as upon initiation of the adaptive immune response.

Alternatively activated macrophages are largely described as beneficial, particularly when it comes to wound healing. Specifically, alternative macrophage activation is responsible for production of extracellular matrix, a property essential in the reparative response. Alternatively activated macrophages are also associated with a reduced expression of pro-inflammatory cytokines, namely TNF α , IL-1b, IL-2, IL-8, IL-12, and CXCL10 (David S. 2011). The response of IL-4 stimulated alternatively activated macrophages is much more characteristic of a TH2-mediated response in comparison to the classical macrophage activation which more closely parallels that of a TH1 response. Despite the previous

characterization of alternatively activated macrophages as a distinct cellular population, emerging evidence indicates the presence of further subtypes under the M2 umbrella and that they are involved in a variety of functions ranging from wound-healing to regulatory functions. In fact, some have described M2 macrophages as actually three distinct subtypes—M2a, M2b, and M2c, each of which is generated through a unique polarization process and performs distinct functions (Figure 4.4) (David S. 2011). M2a and M2c have been attributed clear anti-inflammatory and reparative roles, whereas M2b are somewhat unique in that they produce high amounts of IL-10, an anti-inflammatory cytokine, but low-levels of IL-12, a pro-inflammatory cytokine. Similarly, M2b macrophages may produce TNF α , IL-1 β , and IL-6, indicating a more complex role in the inflammatory response than previously recognized (David S. 2011).

NEURONAL RESCUE

Another critical issue in stroke therapy is how to recover areas of infarcted brain that appear irreversibly damaged due to ischemia. To address this issue, research is now focused on understanding neurogenesis, particularly endogenous repair mechanisms such as the involvement of neuronal progenitor cells and their proliferation and differentiation into neural cells (Wiltrout C. 2007). However, use of a small population of endogenous neuronal progenitor cells and their limited capacity to regenerate under inflammatory conditions may not be enough to achieve significant neurological recovery. Therefore, several growth factors (e.g., epidermal, fibroblast, and vascular endothelial growth factors, erythropoietin) have been tested to increase proliferation and migration of progenitor cells. The major challenge seems to be inducing sufficient proliferation to repair the devastating neuronal damage following ischemia, promoting survival of the newly formed cells in the hostile environment, and more importantly, inducing proper connectivity of the newly formed cells with the existing circuitry (Wiltrout C. 2007). An alternative approach is the transplantation of stem cells, but a number of factors could influence the success of this approach, the main one being the survival of the transplanted cells and the likelihood of their proper differentiation into neuronal cells (Kennea N. L. 2002, Roitberg B. 2004).

FUTURE DIRECTIONS: THERAPEUTIC TARGETING OF MACROPHAGE SUBSETS

Therapeutically, it is clear that shifting from the pro-inflammatory macrophage phenotype, M1, to the anti-inflammatory phenotype, M2, may confer an advantage in both initial injury and long-term recovery. How precisely to alter the phenotype and at what time post-injury is not clear but the idea is promising, particularly considering that recent studies have demonstrated that macrophage subsets may not be truly distinct entities and rather may undergo switching. This idea has been demonstrated *in vitro* in which activating macrophages with LPS resulted in diminished reactivity to subsequent pro-inflammatory stimuli (Lawerence 2011). In contrast, these macrophages maintained the ability to express other genes associated with anti-inflammatory activities such as IL-10. The ability to diminish

responsiveness to pro-inflammatory stimuli while maintaining the anti-inflammatory capabilities is referred to as endotoxin tolerance and is generally associated with a switch from the M1 to M2 phenotype (Lawrence 2011). While inflammation is clearly a promising therapeutic target, our understanding of inflammatory processes and when precisely each event occurs remains somewhat unclear and likely varies across individuals. As such, a need exists for not only improved measurement and insight into inflammatory processes but also a personalized approach, a common theme discussed throughout medical research in recent years. One method for potentially achieving both these goals is the use of blood-based or CSF-based biomarkers.

MOVING FORWARD: CHARTING A COURSE TOWARD NEW STROKE THERAPIES

Tremendous progress has been made in the understanding of fundamental mechanisms of neuronal cell death. However, the translation of these powerful molecular and cellular principles into clinically effective neuroprotective therapies in stroke has been challenging. More recently, emerging data from both experimental and clinical studies now suggest that all cell types in the brain participate in the complex pathophysiology of brain injury following stroke. Consequently, therapeutic approaches should target multiple cell types in an attempt to protect their structural and functional integrity and their reciprocal interactions. Protecting the Neurovascular Unit The so-called “neurovascular unit” provides a conceptual framework that integrates responses in all cell types, including neuronal, glial, and vascular elements (del Zoppo, 2009; Iadecola, 2004; Zaccagna et al., 2008) (Figure 4.5). Cell-cell interactions in the neurovascular unit form the basis of brain function. Dysfunctional signaling in the neurovascular unit underlies the basis for disease. Whereas the intricate molecular pathways of cell death in the neuron have been dissected in detail, the mechanisms of how the entire neurovascular unit responds to stroke are not completely understood. As discussed in the previous sections, cerebral ischemia can rapidly induce perturbations in cell-cell signaling and function within the neurovascular unit. How each cell type succumbs or adapts to injury is dependent on responses in other cells. For example, genomic and proteomic responses in neurons subjected to metabolic stress have been fairly well described. But how each cell type might alter its response to vascular risk factors and ischemia in the context of other elements in the neurovascular unit remains to be elucidated. As the nexus of cell-cell interactions grows, a systems biology approach may eventually be required to rigorously define mechanisms as well as targets for complete neurovascular protection. The importance of cell-cell signaling in the neurovascular unit has been underscored by many studies (Arai and Lo, 2009a, 2009b; Dugas et al., 2008; Eroglu et al., 2009; Guo et al., 2008). Hence, under normal conditions, trophic coupling within the neurovascular unit helps maintain homeostasis. In contrast, under diseased conditions, it is likely that loss of coupling would lead to the pathophysiology (Grammas et al., 1999; Nagai et al., 2007). Loss of trophic coupling is also likely to play a role in the way vascular risk factors render neurons and glia more vulnerable, such as in the link between leukoencephalopathy and brain dysfunction underlying cognitive impairment. Recently, BDNF has been implicated as a candidate factor that mediates trophic coupling between vascular and neuronal compartments (Arai and Lo, 2009b; Guo et al., 2008). So far as BDNF polymorphisms have been implicated in modulating synaptic

plasticity (Kleim et al., 2006), these neurovascular trophic signals may also influence the mechanisms of recovery after stroke.

The concept of the neurovascular unit may provide an integrated framework for investigating mechanisms and therapies. Salvaging neurons alone may not be sufficient. One has to protect glial and vascular elements as well. Future investigations might be better served by pursuing targets that are expressed on multiple cell types in brain. Furthermore, prevention of cell death alone may also not be sufficient. In order for therapies to be clinically meaningful, cellular function must be preserved and/or restored. Neurons that are alive but lack proper connectivity or do not express the correct array of transmitter release-reuptake and synaptic activity may not be functional.

Astrocytes that survive, but cannot provide hemodynamic coupling would be unable to link neuronal activation with the required vascular responses. Oligodendrocytes that are respiring but metabolically impaired might not provide the necessary myelination for axonal conduction. Endothelial cells that survive but do not maintain blood-brain barrier properties would facilitate damage to adjacent parenchyma. Ultimately, any stroke therapy must include both prevention of cell death as well as rescue of integrated neurovascular function. Ischemic tolerance and postischemic hypothermia are some of the most potent protective strategies for ischemic brain injury and represent examples of multimodal therapies targeting the neurovascular unit as a whole. These are described in the next sections.

Figure 4.5. *Remodeling the Neurovascular Unit*: This schematic depicts a cerebral blood vessel and surrounding brain parenchyma that comprise the neurovascular unit. The neurovascular unit encompasses cell-cell and cell-matrix interactions between component vascular, glial, and neuronal cells. Homeostatic signaling in the neurovascular unit sustains normal brain function. Dysfunctional neurovascular signaling mediates injury after stroke. During the recovery phase after stroke, neurovascular signaling may also be critically important with repair mechanisms that may involve angiogenesis, vasculogenesis, and endothelial precursor mechanisms. As the blood-brain barrier heals, inflammation may convert from a deleterious to beneficial role. Reactive glia (astrocytes, microglia, pericytes) may secrete trophic factors. Synaptic and dendritic plasticity as well as axonal remyelination may provide parenchymal substrates for functional recovery. Emerging data now suggest that these phenomenon do not occur in isolation. All components of the neurovascular unit are likely to remodel coordinately (Arai et al., 2009; Murphy and Corbett, 2009; Zhang and Chopp, 2009).

HOW DOES THE BRAIN PROTECT ITSELF? LESSONS FROM ISCHEMIC TOLERANCE

Some of the very same mechanisms implicated in the tissue damaging responses after stroke can also be engaged to protect the brain after threatened injury and to induce ischemic tolerance (IT). IT is a concerted organ response to protect itself against tissue injury and has been widely studied over the past three decades in an effort to identify endogenous mechanisms of protection and to exploit them for therapeutic purposes (Obrenovitch, 2008). In its delayed form, it is induced after challenge by a subthreshold noxious stimulus, developing within 1–3 days and lasting for several additional days. Experimentally it can be induced by exposure to preconditioning stimuli such as neurotoxins (e.g., glutamate), substrate deprivation (e.g., ischemia, hypoxia), or inflammation (e.g., cytokines and immune responses) and engages mechanisms that detect, transduce, and promote a complex tissue reaction that reflects a fundamental genomic reprogramming after threatened injury (Dirnagl et al., 2009; Gidday, 2006; Stenzel-Poore et al., 2004). In this altered physiological state, tissue damage is mitigated when challenged by exposure to a wide range of deleterious stimuli, even if unrelated to the initial challenge. It is mediated by highly redundant cellular, molecular, and physiological mechanisms involving neurons, astrocytes, and vascular cells (Gidday, 2006). Upstream sensors have been implicated, including adenosine and its A1 receptor, the NR2A NMDA receptor subunit, and the transcriptional regulator hypoxia inducible factor (HIF). HIF is an attractive candidate because it regulates a constellation of genes, including those whose protein products facilitate oxygen transport (erythropoietin), regulate glycolytic metabolism (e.g., glucose transporters), and promote angiogenesis (e.g., VEGF), by way of example.

Unexpectedly, genetic deletion of HIF1a improves infarct volume after middle cerebral artery occlusion, implicating as yet unknown pathogenic mechanisms activated by ischemia (Helton et al., 2005). Erythropoietin, one of the gene products of HIF1a, promotes PI3 kinase/AKT activity and the expression of NFkB-dependent protective genes (Digicaylioglu and Lipton, 2001).

Erythropoietin also downregulates hypoxia-induced proapoptotic mechanisms (Noguchi et al., 2007; Prass et al., 2003; Ruscher et al., 2002), and erythropoietin-based therapies have been investigated in the clinical arena (Ehrenreich et al., 2009). Heat shock protein family members are upregulated in ischemic tolerance and, based on their multiple cytoprotective actions, may promote survival. Preconditioning stimuli preserve connexin hemichannels in astrocytes facilitating ATP released from these cells and increasing the extracellular concentration of the beneficial nucleoside adenosine (Lin et al., 2008).

At the same time, preconditioning safeguards the function of cerebral blood vessels from the deleterious effects of cerebral ischemia, resulting in improved penumbral flow and reduced brain damage (Kunz et al., 2007b). These astrocytic and vascular changes are coupled with mechanisms that reduce energy demands, lessen inflammatory responses and ion channel activity, and decrease cascades promoting blood clotting and apoptotic cell death (Dirnagl et al., 2009; Obrenovitch, 2008; Gidday, 2006). Factors involving mitochondria as well as its uncoupling proteins have also been suggested and include improved efficiency of ATP synthesis, preservation of the mitochondrial membrane potential, and delayed opening of mitochondrial transition pore formation, as well as opening of mitochondrial ATP-

dependent K⁺ channels (Dirnagl and Meisel, 2008). One of the key questions defying explanation at the moment is how and why diverse preconditioning stimuli targeting single genes or key steps in seemingly unrelated cascades all impact infarct injury in genetically engineered and wild-type mice. It may be telling us that the mechanisms through which the brain protects itself involve a highly integrated network response that emphasizes multiple cells within the neurovascular unit. If true, comparable multicellular approaches are needed that capitalize on this integrated response in the design of successful treatments.

THERAPEUTIC HYPOTHERMIA: ENGAGING PLEIOTROPIC MECHANISMS IN MULTIPLE CELL TYPES

The therapeutic hypothermia field has advanced significantly during the past decade, inspired by positive outcomes from clinical trials in cardiac arrest victims (Bernard et al., 2002). Satisfactory neurological recovery was achieved in about half of the treated patients when treatment was begun within 2 hr of cardiac arrest. Promising results were reported in small feasibility studies in neonatal ischemia (Shankaran et al., 2005). Current efforts are directed toward translating these successes in cardiac arrest and neonatal ischemia to patients with ischemic stroke, but there remain unresolved technical issues surrounding the timing and method for inducing hypothermia, and the deleterious effect of rewarming (Wagner and Zuccarello, 2005). It is now well accepted that hypothermia reduces ischemia in animal models of stroke, and so far, preclinical results have helped guide the design of clinical trials in human subjects. Combining hypothermia with thrombolysis is one example. Experimental evidence suggests that hypothermia protects the brain through pleiotropic effects, acting on multiple cell types within the neurovascular unit. Hypothermia reduces brain metabolism, thereby significantly decreasing oxygen consumption and the workload of the entire organ (Sakoh and Gjedde, 2003). Hypothermia also reduces glutamate release, ROS production, and peri-infarct depolarizations. Inflammatory markers decrease, as well as microglial activation, leucocyte infiltration, MMP activation, and BBB disruption. In addition, hypothermia suppresses apoptotic cell death, decreases mitochondrial release of cytochrome C and apoptosis inducing factor (see for review Tang and Yenari, 2010). Cell survival pathways are upregulated and appear to contribute to the multiplicity of neuroprotective mechanisms. To what extent each of these promotes tissue protection or interacts synergistically to enhance tissue survival is not known and remains for further investigation. Nevertheless, therapeutic hypothermia does illustrate the potential power of approaching stroke therapy using combinations of modalities that engage multiple cell types to enhance protection and recovery.

GAINING INSIGHT FROM THE BEDSIDE: UTILITY OF BIOMARKERS

Biomarkers for Diagnosis and Prognosis

With the recent advances in technology and research, many look for biomarkers as a new avenue to further understand, diagnose, and treat diseases. A biomarker is a biological

component that can be tangibly quantified to understand normal or pathological functioning in the body (Figure 2) (Bettermann K. 2011, Mayeux R. 2004). The roles of biomarkers in the laboratory and clinical setting are vast. They can be used in diagnosing pathologies, monitoring progress of disease or injury, identifying targets for intervention, and assessing risk of pathology. The measurement of biomarkers translated successfully from bench-to-bedside with troponin-1, a well-known example of a biomarker used to aid in diagnosis of myocardial infarction (Than M. 2012). Within the neuroscience community, biomarker research has become an area of increased interest and investigation for a variety of pathologies ranging from stroke to traumatic brain injury (TBI) to Alzheimer's disease (AD).

Figure 4.6. *Potential uses of biomarker in Stroke*: Potential uses of biomarkers include identification of stroke cause, type, and severity allowing for potential diagnosis, prognostication, and therapeutic selection or monitoring (theranosis). Biomarkers may also play a role in understanding disease pathophysiology, particularly in regards to inflammation and macrophage release and/or polarization.

The remainder of our discussion of biomarkers will focus on ischemic stroke, but it is important to recognize the similarities of many disease states, particularly stroke and TBI. Timing of an accurate diagnosis is essential for patients with stroke. The only FDA-approved treatment, tissue plasminogen activator (tPA), has traditionally had a 3-h window for administration after onset of stroke (Weant K. A. 2012). While recent guidelines suggest up to a 4.5 h window (Lansberg M. G. 2012), tPA administration has the potential to result in numerous well-documented adverse effects, such as hemorrhagic transformation (HT) or even death (Montaner J. 2011). Consequently, numerous contraindications for tPA administration exist and many patients go untreated. The identification of biomarkers for stroke therefore may not to be limited to traditional diagnostic or prognostic avenues but also more appropriate identification of patients at risk for tPA-associated morbidities.

Likewise, biomarkers may also be useful in determining patients in which tPA administration may be beneficial despite the presence of a comorbidity or risk-factor that would normally result in exclusion from tPA-based treatment. Previous studies have demonstrated differences in numerous markers that may one day potentially play a role in detection of ischemic stroke, stroke-mimic, and transient attack, as well as predict patient outcome (Navaro Sobrino M. 2011, Quin L. 2012), determine stroke severity, predict the risk of recurrent stroke (Tsai T. H. 2012) or hemorrhagic transformation (HT) (Ramos-Fernandez M. 2011) increase understanding of pathophysiology behind cerebral ischemia (Vangilder R. L. 2012), and provide possible targets for therapeutic intervention (Denes A. 2011). While additional studies are certainly required to elucidate the most appropriate use of the markers discussed in the cited studies, each of these studies has provided valuable insight and potential examples of biomarker utilization at various time-points in the therapeutic or prognostic decision-making process, particularly as related to patient suitability for tPA administration. Historically, biomarker-based studies sought the identification of a single marker for diagnostic/prognostic purposes. However, the investigated biomarkers have proven to be not specific or sensitive enough across multiple populations for clinical usage. Thus, researchers have transitioned largely towards identification of a panel of biomarkers rather than a single marker. The discovery of a group of biomarkers, instead of a sole marker, may improve the specificity, sensitivity, and prediction values across time (Ramos-Fernandez M. 2011, Bettermann K. 2011). A panel could therefore additionally provide the healthcare provider with more information than a single biomarker could reliably do alone (Ramos-Fernandez M. 2011). Due to biomarker discovery and investigation being a relatively new field, our discussion below is limited primarily to single marker studies.

Multiple biomarkers of stroke have been identified in the literature. A popular biomarker of note is matrix metalloproteinase 9 (MMP-9). High levels are correlated with current neurological deterioration, stroke severity, and infarct size (Montaner J. 2001). Interestingly, before administration of tPA, high levels also have been shown to accurately predict HT (Castellanos M. 2003, Montaner J. 2003). Despite MMP-9 playing a clear role in stroke pathology, a major pitfall of its use in the clinical setting is that it is not specific to the brain. It is involved with inflammation and matrix remodeling throughout the body and in different pathologies such as diabetes, hypertension (Tayebjee M. H. 2004), atherosclerosis (Sundstrom J. 2006), and many others. Therefore, MMP-9 likely cannot be used as a stand-alone biomarker for stroke; however it may be a helpful addition to a biomarker panel. Another biomarker of note is glial fibrillary acidic protein (GFAP). High levels of GFAP have been found to be indicative of hemorrhagic stroke in the acute stage, and therefore,

GFAP may be an important biomarker to consider when deciding the appropriateness of thrombolytic administration (Hasan N. 2012). Importantly unlike MMP-9, GFAP is released strictly by astrocytes in the brain (Marginean I. C. 2011). Outside of stroke, GFAP possesses prognostic value for outcome in cases of mild and severe traumatic brain injuries, though it is suggested that it is not an independent factor (Metting Z. 2012, Wiesmann M. 2010). A high concentration of S100 calcium binding protein (S100B) also has the ability to distinguish between hemorrhagic and ischemic stroke (Montaner J. 2012) and positively correlates with infarct volume (Jonsson H. 2001). When measured along with MMP-9, Glickman and colleagues revealed that S100B levels can differentiate between ischemic stroke and stroke mimic (Glickman S. W. 2011). Yet also like MMP-9, evidence indicates that S100B is expressed outside of the brain, such as in cancer, and therefore suffers from the same lack of specificity associated with other markers previously mentioned (Peric B. 2011, Strobel K. 2007). D-dimer concentration shows promise as a biomarker of stroke. As a component of a blood clot, d-dimer is useful for diagnosing the subtype (Hirano K. 2012), specifically cardioembolic stroke (Alvarez-Perez F. J. 2011), and distinguishing between ischemic stroke and stroke-mimic (Montaner J. 2011). As a thrombotic biomarker, d-dimer has many uses in regards to stroke, but it too is found throughout the body and, therefore, is not reflective solely of central nervous system events. Regardless, d-dimer has proven useful in the diagnosis of post-stroke cardiovascular complications such as pulmonary embolism, deep vein thrombosis and others (Glickman S. W. 2011).

The idea of individualized therapy, particularly when it concerns the selection of patients for thrombolytic therapy, has been further explored in recent years by Ning and colleagues. They showed significant prolonged effects on cellular signaling following tPA as evident by prolonged patterns of degradomic protein expression up to 5 days post-treatment, a finding in distinct contrast to that of non-tPA treated stroke patients in which a hyperacute response was evident but ceased by 24 h (Ning M. 2010). Besides demonstrating widespread effects of tPA on the extracellular matrix and brain parenchyma, far outside of the acute therapeutic window, their work could potentially demonstrate the utility of biomarkers in identification of patients at risk for adverse effects following therapeutic administration.

Biomarkers for Elucidating Disease Pathophysiology

While biomarkers are often thought of primarily for diagnostic and prognostic purposes, emerging work indicates a potentially greater role for biomarkers in elucidation of disease pathophysiology, especially communication between the brain and systemic responses. For example, Hayakawa and colleagues showed that by disrupting either the release of high-mobility-group-box-1 (HMGB1) from reactive astrocytes, or the HMGB1 receptor on endothelial progenitor cells, neurovascular remodeling is altered, and worsened deficits result (Hayakawa K. 2012). This work demonstrates the ability to isolate cell-specific events by taking in vitro based findings, such as the release of HMGB1 into astrocyte-conditioned media, and applying them to in vivo studies to determine the effect of HMGB1 systemically on post-ischemic injury. Other studies have used in vitro models in a similar fashion to demonstrate complex signaling relationships amongst neurons and glia. Specifically, Chu et al. showed the protective role of factors released by ischemic microglia, astrocytes, and neurons on astrocytes subjected to ischemia (Chu L. F. 2008). While space constraints

prevent the mention of all applicable works, studies such as those described illustrate the potential for an expanded role of biomarkers in elucidation of disease pathophysiology and crosstalk between various cells within the brain and systemically.

KEY ADVANCES IN STROKE

■ ■ ST-3 reinforces the need for further efforts to increase the proportion of ischaemic strokes treated within 3 h, but provides reassurance that thrombolysis in elderly patients or within 6 h from stroke onset does not increase mortality (Sandercock, P. 2012)

■ ■ Under the conditions of the ICTUS trial, citicoline is not effective in the treatment of moderate to severe acute ischaemic stroke (Dávalos, A. 2012)

■ ■ Atrial tachyarrhythmia must be considered as a new source of embolism in patients with cryptogenic stroke (Healey, J. S 2012)

■ ■ Patent foramen ovale closure with a device did not offer a greater benefit than medical therapy alone for the prevention of recurrent stroke or TIA (Takahashi, K. 2006)

■ ■ An animal study provides the first evidence that transplantation of cells derived from human induced pluripotent stem cells is a safe and efficient approach to promote recovery after stroke (Oki, K. 2012)

Several clinical trials and experimental studies that could have a major impact on the treatment of patients with ischaemic stroke were published in 2012. The studies cover all therapeutic options, including stroke prevention, recanalization and thrombolysis, neuroprotection, and promising new therapeutic approaches focused on neurorepair. Despite improvements in its management in recent years, cerebrovascular disease remains a major cause of mortality and morbidity. The current framework of therapeutic options to prevent or treat stroke comprises a spectrum of five fields of treatment—primary prevention, recanalization and thrombolysis, neuroprotection, secondary prevention, and neurorepair (Figure 5.6). In 2012, we witnessed developments in all five areas, with important implications for stroke treatment. When primary prevention fails, an effective protocol for acute stroke treatment is imperative, early reperfusion of ischemic tissue being the primary goal. Currently, thrombolytic therapy with recombinant tissue plasminogen activator (rtPA) is the most effective approach. However, the extensive exclusion criteria, together with the short therapeutic window and narrow age range, severely restrict its use. The Third International Stroke Trial (IST-3) (Sandercock, P. 2012) was conducted to establish the balance between benefits and harms of rtPA treatment in patients who did not accomplish the licence criteria and, hence, to determine whether a wider range of patients might benefit up from rtPA up to 6 h from stroke onset. IST-3 enrolled 3,035 patients (1,515 in the rtPA group and 1,520 controls), 53% of whom were aged >80 years. No differences were found between groups with respect to the primary end point (37% in the rtPA group versus 35% of controls survived and achieved independence).

The global benefits of rtPA treatment seemed to be greatest within the first 3 h from stroke onset, but the analyses had insufficient power to define the benefit in a therapeutic window beyond 3 h. Interestingly, treatment efficacy was similar between patients older and younger than 80 years.

Figure 5.6. *Recent advances in stroke*: Spectrum of therapeutic options to prevent or treat stroke. In 2012, key advances were made in stroke prevention (primary and secondary), recanalization and thrombolysis, neuroprotection, and neurorepair strategies. Abbreviation: iPS, induced pluripotent stem.

The IST-3 data reinforce the need for further efforts to increase the proportion of ischemic strokes treated within 3 h, but they provide reassurance that rtPA treatment in elderly patients and within 6 h from stroke onset does not increase mortality. Although clinical trials with neuroprotective agents have systematically failed, neuroprotection remains a treatment option for acute ischemic stroke. In 2012, the results of ICTUS (International Citicoline Trial on acUte Stroke) were published (Dávalos, A. 2012). In this trial, patients with moderate to severe acute ischemic stroke were treated with either citicoline or placebo within 24 h after symptom onset. The primary outcome was recovery at 90 days measured by a global test combining three measures—NIH Stroke Scale score ≤ 1 , Modified Rankin Scale score ≤ 1 , and Barthel Index score ≥ 95 —in accordance with a pooled meta-analysis of previous randomized trials with citicoline.

(Dávalos, A. 2002) 2,298 patients (1,148 assigned to citicoline and 1,150 to placebo) were enrolled in ICTUS.2 Global recovery was similar in both groups, and no significant differences were reported in the safety variables or the rate of adverse events. Although ICTUS followed a protocol nearly identical to that of the pooled meta-analysis, (Dávalos, A. 2002) with minimal differences in statistical analysis, none of the benefits for citicoline were confirmed. However, the previous clinical trials with citicoline were conducted 10 years ago, and the standard of stroke care has substantially improved in the meantime. Also, the patients in ICTUS were, on average, 4 years older, and were over three times more likely to have received rtPA treatment, than those in previous trials. Comparison with the older studies suggests that the benefits of citicoline have become diluted in parallel with improvements in the standard of care for acute ischaemic stroke—a fact that should be taken into account for future trials of neuroprotective drugs.

To initiate appropriate secondary prevention, it is essential to know the cause of stroke, yet at least one-quarter of strokes are still classified as cryptogenic. The ASSERT investigators recruited 2,580 individuals >60 years without a history of atrial fibrillation (AF) in whom a pacemaker or defibrillator had been implanted. (Healey, J. S 2012) Patients were monitored for 3 months to detect subclinical atrial tachyarrhythmias (ATs; episodes of atrial rate >190 bpm for >6 min), and were followed up for a mean of 2.5 years for the primary outcome of ischemic stroke or systemic embolism. At least one AT was detected in 10.1% of patients. During the follow-up period, 4.2% of patients in whom subclinical AT had been detected had an ischemic stroke or systemic embolism, compared with 1.7% in whom subclinical AT was not detected. The attributable risk of ischemic stroke or systemic embolism associated with subclinical AT was 13%, which is similar to the stroke risk associated with AF (Wolf, P. A. 1991) On the basis of these results, AT must be considered as a new source of embolism in patients with cryptogenic stroke.

The prevalence of patent foramen ovale (PFO) ranges from 20–26% in the general population, but may be as high as 56% in patients under 55 years who have experienced a cryptogenic stroke. (Lamy, C. 2002) The CLOSURE I investigators evaluated the potential benefits of percutaneous device closure versus medical therapy for secondary stroke prevention in patients with PFO (Furlan, A. 2012) This multicentre, randomized, open-label trial compared PFO closure (using the STARFlex device) with medical therapy (warfarin, aspirin or both) in patients 18–60 years of age with PFO who had presented with cryptogenic stroke or TIA within the previous 6 months.

The primary end point was a composite of stroke or TIA during 2 years of follow-up, death from any cause during the first 30 days, or death from neurological causes between 31 days and 2 years. 909 patients—447 percutaneous device and 462 medical therapies—were enrolled. At 2 years, effective closure was maintained at 86.7% of cases. The incidence of the primary end point was 5.5% in the percutaneous device group and 6.8% in the medical group. Stroke incidence was 2.9% in the percutaneous device group and 3.1% in the medical group. No deaths occurred by 30 days in either group, and there were no deaths from neurological causes during the 2-year follow-up period. AF was significantly more frequent in the closure group (5.7% versus 0.7%). In conclusion, closure did not offer greater benefits than medical therapy alone for the prevention of recurrent stroke or TIA. Over the past two decades, stem cell based neurorepair has emerged as a promising therapeutic option for ischemic stroke.

Animal experimental data with embryonic stem (ES) cells, neural progenitor cells or bone marrow-derived progenitor cells are encouraging; however, no proven stem cell-based therapy is currently available for stroke. Despite the supposed immune-privileged status of the CNS, allogeneic grafts of stem cell-derived neurons and glia remain susceptible to rejection.

A novel alternative strategy to avoid graft rejection and immunosuppression is to generate induced pluripotent stem cells (iPSCs) from somatic cells. In 2006, it was reported that skin fibroblasts from adult mice could be reprogrammed to a pluripotent state by retroviral expression of four transcription factors (Takahashi, K. 2006). The resulting iPSCs are indistinguishable from ES cells in morphology, proliferative capacities, surface antigens, gene expression, epigenetic status, and telomerase activity. The Nobel Prize in Physiology or Medicine 2012 was awarded to Sir John B. Gurdon and Shinya Yamanaka for this breakthrough. The Laboratory of Neural Stem Cell Biology and Therapy, Lund, Sweden

transplanted long-term self-renewing neuroepithelial-like stem cells, generated from adult human fibroblast-derived iPSCs, into stroke-damaged mouse and rat striatum or cortex. (Oki, K. 2012).

The transplanted cells stopped proliferating, could survive without forming tumors for at least 4 months, and differentiated into morphologically mature neurons. Grafted cells exhibited electrophysiological properties of mature neurons and received synaptic input from host neurons. Most importantly, the recovery of forepaw movements was observed by 1 week after transplantation. This study provides the first evidence that transplantation of human iPSC-derived cells is a safe and efficient approach to promote repair and recovery after stroke.

CURRENT DEVICES USED FOR MECHANICAL EMBOLUS REMOVAL IN CEREBRAL ISCHEMIA

The mechanical embolus removal in cerebral ischemia (MERCI) trial evaluated the efficacy and safety of a mechanical endovascular device (which consists of a Nitinol core wire with shaped loops at the distal end designed to engage the thrombus) in the revascularization of an occluded large cerebral vessel within 8 hours of stroke onset (Figure 5.7) (Smith W. 2005 and 2008). The original study was subsequently updated with the Multi-MERCI trial incorporating a newer generation of the device (Smith W. 2008). The population of patients included in both studies were those ineligible to receive IV tPA (either arriving too late or having a contraindication for its use). The MERCI trial was a multicenter, prospective, single-arm trial that referred to the control arm of the PROACT II trial as historical control. Although the therapeutic window was 8 hours, the median time from onset to treatment was 4.3 hours in both studies. The recanalization rate was significantly higher than that in the control arm of PROACT II (48% vs 18%, respectively), but lower than that in the IA tPA group (66%). The proportion of patients achieving mRS2 at 90 days was comparable to that in the control arm of PROACT II (22.6% vs 25%, respectively). In contrast, the mortality rate of 43.5% was significantly higher than that reported in most prospective studies of the treatment of acute stroke. The investigators attributed this elevated mortality to a higher baseline NIHSS score (median 18) and higher proportion of basilar artery and internal carotid artery terminus occlusions. The introduction of a new generation of the device in the Multi-MERCI trial resulted in a significantly higher recanalization rate (55%) and an improvement in the mortality or neurological outcome at 90 days, although statistically insignificant.

PENUMBRA DEVICE

The Penumbra device was introduced in the United States in 2008 after results from a European safety trial were published (Figure 5.8) (Penumbra Pivotal Stroke Group 2009). The system consists of a thrombus debulking and aspiration component as well as a direct thrombus extraction component. The safety and efficacy of the device were reported in a multicenter, prospective, single-arm trial with the goal of establishing substantial equivalence to its predicate device—the Merci clot retrieval system.

Although the revascularization rate using the Penumbra device was the highest of the prospective trials at 81.6% (compared with 55% in the Multi-MERCI trial and 66% in the PROACT II trial), the neurological outcome was comparable or lower (25% with mRS 2, vs 36% in the Multi- MERCI trial and 40% in the PROACT II trial).

Figure 5.7. (A) *Merci Retriever device* which is a corkscrew-shaped product designed to remove blood clots from large vessels in patients experiencing acute ischemic stroke. (B) *Endovascular Therapy for acute stroke*: The principle of clot retrieving. The Merci System. Endovascular therapy for acute stroke is always performed under general anesthesia. First the MerciBalloon Guide Catheter is placed in the common or internal carotid artery for anterior circulation occlusion. Using standard cerebral catheterization techniques, a microcatheter is guided then through the guide catheter into the occluded vessel and passed beyond the thrombus (a). The Merci Retriever is now advanced through the microcatheter, and several of the helical loops are deployed distal to the thrombus. The Merci Retriever is then retracted to the face of the thrombus, and the proximal loops are deployed within the thrombus (b). The balloon of the Merci Balloon Guide Catheter has to be inflated now to arrest orthograde blood flow during removal of the thrombus. At least the Merci Retriever with the ensnared thrombus and the microcatheter are withdrawn together into the balloon guide catheter lumen. Continuous aspiration is applied to the guide catheter to promote complete evacuation of the thrombus (c). Once a retrieval attempt is completed, the balloon of the balloon guide catheter is deflated to re-establish flow. If the clot could not be removed with the retriever, the procedure can be repeated up to 5 times.

Figure 5.8. Penumbra Device.

The investigators attribute this disparity to the lack of sufficient power and higher baseline NIHSS score.

STENT-ASSISTED RECANALIZATION IN ACUTE ISCHEMIC

Stroke The use of endovascular stents has been recently advocated in the setting of acute stroke (Levy E. 2009). Based on retrospective data regarding the use of intracranial stents as a salvage technique in acute stroke, the SARIS trial (stent-assisted recanalization in acute ischemic stroke) aimed to evaluate the safety of stent deployment as a primary therapeutic intervention for acute stroke using a prospective, single-arm study design.

The investigators used the Wingspan (Boston Scientific, Natick, MA) and the Enterprise (Cordis, Bridgewater, NJ) intracranial self-expanding stents.

All 20 cases included in the trial were successfully revascularized, although 60% of patients required the use of an adjuvant intraprocedural pharmacological infusion (eptifibatide or tPA) or angioplasty. The risk of subsequent asymptomatic and symptomatic hemorrhage was 10% and 5%, respectively, and no procedure-related complications were reported. With regard to neurological outcomes, 45% of patients achieved an mRS score of 1 or less at 1 month follow-up. The results of the SARIS trial are difficult to directly compare with the large randomized prospective trials because it included a small number of patients with a relatively low median NIHSS score (13% vs 19% in IMS II and 17% in PROACT II), was

nonrandomized, and included only short follow-up; nonetheless, the results represent an encouraging foundation for further investigation into the role of stenting for stroke treatment

FUTURE DIRECTIONS IN STROKE THERAPY: LOGISTICS OF CARE

Improved stroke care begins at the pre-hospital stage; The California Acute Stroke Prototype Registry investigators estimate >10-fold increase in the number of patients receiving appropriate treatment if the hospital arrival time is within 1 hour of symptom onset, (California Acute stroke Pilot Registry (CASPR 2005)) highlighting the importance of public education and emergency medical services response time.

Future first responders to the scene of a suspected stroke may be able to perform real-time neuroimaging rapidly with subsequent transmission of images to the receiving medical center such that the time to diagnosis, triage, and catheterization (if deemed necessary) is optimized. Real-time neuroimaging using transcranial ultrasonography, especially with the concurrent use of ultrasonography contrast agents, may prove beneficial in providing such rapid assessment of occluded cerebral vessels in the field (Seidel G. 2009) Color-coded duplex ultrasonography has been shown to correctly differentiate hemorrhagic stroke from ischemic stroke in 95% of cases when compared with computed tomography scanning (Maurer M. 1998). Furthermore, the use of cerebroprotective agents, again possibly administered in the field or early in the provision of stroke care, may further contribute to improved outcomes. With our current knowledge, patients arriving at a stroke treatment center outside of the defined windows for thrombolysis have few options outside of future stroke prevention and rehabilitation; therefore, extension of the therapeutic window is critical for allowing more patients to benefit from acute stroke treatment. The replacement of the traditional “stopwatch” approach to stroke with a more dynamic and functional time window is likely to take place, with growing evidence in clinical trials with the usefulness of magnetic resonance imaging-based patient selection for thrombolysis (desmoteplase in acute ischemic stroke (DIAS), diffusion and perfusion imaging evaluation for understanding stroke evolution (DEFUSE), and dose escalation of desmoteplase in acute stroke (DEDAS) trials) (Goldberg M. 2012). The ongoing Third International Stroke Trial and Mechanical Retrieval and Recanalization of Stroke Clots Using Embolectomy (MR RESCUE) trial will also likely impact whether future patients are offered thrombolysis outside the conventional window.

TECHNOLOGICAL ADVANCES

The incorporation of interventional approaches as an adjunct or alternative to intravenous thrombolysis in the setting of acute stroke is a rapidly growing field with a recent explosion in the number of devices available to the interventionalist. The PROACT trial was one of the first large multicenter trials to investigate the use of intravenous thrombolytic agents for the treatment of acute stroke; the study was followed by several other randomized trials, including the IMS study, which described the use of IV tPA as a bridge toward catheter-directed arterial infusion of the thrombolytic. IMS II introduced data regarding the use of low-energy sonography in addition to local thrombolysis. Subsequent studies have evaluated

mechanical clot retrieval devices, including the MERCI and Penumbra trials (Goldberg M. 2012). Investigations and breakthroughs are likely to continue in both pharmacological and mechanical thrombolysis, with the future generation of devices likely to include a combination of the 2 modalities to achieve increased recanalization rates (Hopkins L. 2008, Sugrue P. A. 2009). Future devices are also likely to address the issue of distal emboli during clot manipulation (Leibig T. 2008). In addition to clot removal and microinfusion devices, the use of retrievable stents for the acute revascularization of thromboembolic stroke is a topic of great interest that is currently being evaluated (Wakhloo A. 2008, Zaidat O. O. 2008). Stenting may prove useful as an adjunct to thrombolysis for immediate reperfusion with subsequent retrieval, or alternatively left in place for permanent deployment.

PHARMACOLOGICAL ADVANCES

Promising pharmacological options for the treatment of acute ischemic stroke can be organized in 1 of 3 categories:

1. Novel thromboembolic agents and adjuvants (including antiplatelet and anticoagulation agents). Microplasmin, a recombinant form of human plasmin, may have a reduced propensity to cause bleeding compared with tPA and has been shown to be tolerable in human volunteers and efficacious in animal models of stroke. Microplasmin is currently under investigation to determine the clinical efficacy in human acute ischemic stroke patients (Thijis V. 2009).
2. Neuroprotective agents that have been an attractive but so far elusive target. At the time of this writing, more than 160 trials for ischemic stroke neuroprotective agents have been initiated (Internet Stroke Centre W. U. 2010). Unfortunately, few have produced positive results. However, notable recent exceptions include high-dose human albumin therapy, which showed promising results in the original Albumin in Acute Stroke trial (Palesch Y. Y. 2006). A larger randomized multicenter placebo-controlled efficacy trial is now underway (Goldberg M. 2012). Additionally, magnesium, which has been shown so far to be a rather weak neuroprotectant, (Muir K. W. 2004) continues to be under investigation because it is a safe and relatively inexpensive agent that may be administered in the hyperacute pre-hospital setting or during interventional procedures (Goldberg M. 2012)
3. Agents that contribute to the recovery of lost or dormant neuronal function. Although currently at its infancy stages, future interventional approaches may include local administration of neurorestorative agents, such as stem cells of both exogenous and endogenous origins, or neurotrophic molecules that promote and direct endogenous neurogenesis (Burns T. C. 2009, Chen J. 2001).

CONCLUSION

The lack of successful therapeutic translation from bench-to-bedside for a devastating disease such as stroke, despite the progression of over 100 proposed therapeutics to clinical

trials, necessitates a closer review of both how stroke research is conducted as well as the therapeutic targets selected. While preclinical studies have improved in rigor, particularly with the advent of the Stroke Therapy Academic and Industry Roundtable (STAIR), clear deficiencies remain. Perhaps most notably, the lack of emphasis on the aging process and commonly associated comorbidities found in stroke patients, is persistent throughout the literature. As aging is the greatest risk factor for stroke, and numerous works have identified a role of aging in response to injury, inclusion of more preclinical models utilizing aged animals may lead to the development of promising therapeutics. Other promising avenues of investigation into stroke research include the role of glia, particularly with regards to the inflammatory response.

Stroke remains a major public health issue, and thrombolysis have been proven effective as therapy for cerebral ischemia, either administered intravenously within 3 hours or intra-arterially within 3 to 6 hours. Whereas the development of new thrombolytic agents and regimens as well as the rapid evolvement of endovascular therapies are an exciting component of the future of stroke treatments, one of the main challenges remains the wide availability and use of treatment for acute stroke patients. Even in its most basic version, intravenous thrombolysis has been demonstrated to be effective and safe when used in small medical centers. The advent of telemedicine and the use of robotics play an important role in making the therapy available to all stroke patients, as does community education, training of primary care providers, allied health professionals, and emergency medical services.

A number of promising thrombolytic strategies are currently being investigated, which may push the field further forward, including the following: The pilot nonrandomized safety and feasibility study, Interventional Management of Stroke, analyzed a combination of intravenous and intra-arterial thrombolysis, bringing together the speed of initiation of intravenous therapy and the higher recanalization rates of intraarterial thrombolysis. Endovascular therapies are rapidly evolving and continue to offer patients in whom intravenous thrombolysis fails a real chance at recanalization. These developments are of great importance to the endovascular neurosurgeon, and it is expected that as a result, endovascular neurosurgeons will be intimately involved in the treatment of stroke patients in the futures. And finally, ultrasound enhanced thrombolysis, developed by Alexandrov et al., using high-frequency ultrasonography to accelerate enzymatic fibrinolysis by increasing penetration of drug molecules into the clot, may offer an enhanced noninvasive option of effective thrombolysis.

Promising preclinical studies and early phase clinical studies, such as the work with minocycline, indicate a potential protective effect associated with microglial inhibition. Similarly, astrocytic modulation via administration of arundic acid may result in improved outcome. Other areas of investigation with regards to inflammation, such as understanding how to manipulate macrophage polarization for therapeutic benefit may lead to breakthroughs in drug development. Lastly, biomarker discovery, while often thought of in a diagnostic or prognostic sense, may in fact serve a much broader role in understanding disease pathophysiology and therapeutic selection. By improving preclinical models to more accurately emulate the clinical scenario and targeting disease pathophysiology beyond the nearly immediate events, the likelihood of successful translation from laboratory to clinic may be improved.

Neurointerventional surgery for the treatment of ischemic stroke is a rapidly expanding field with constantly improving tools and ever evolving indications. Recanalization rates

appear to be on the rise in more recent studies compared to early studies. As data continues to accumulate regarding new treatment modalities and technologies, neurosurgeons, radiologists and neurologists should come together to design new treatment paradigms. Much work remains to streamline the care of stroke patients so that appropriate patients can be treated in a timely manner. The advances described above reflect progress across the spectrum of therapeutic options in stroke, from primary prevention to neurorepair. Every step takes us towards the ultimate aim of better outcomes and quality of life for patients with stroke.

ABSTRACT

Stroke is a leading cause of death and disability worldwide. Stem cell therapy is an emerging therapeutic modality with evidence of significant benefits in preclinical stroke models. A number of phase I and II clinical trials have now been completed, with several more currently under way. Translation to the bedside, however, remains a long way off, and there are many questions that remain unanswered. This chapter will summarize the current evidence and ongoing clinical trials worldwide, and explore the challenges to making this a realistic treatment option for the future. Despite advances in acute care and secondary preventive strategies, stroke remains a major burden on health-care resources worldwide. Thrombolysis with tissue plasminogen activator is now a well-established treatment for acute ischemic stroke and is associated with significant improvements in outcomes. However, its use is limited to a narrow time window of only 4.5 hours from symptom onset, and in the UK only 5% of stroke patients currently receive this treatment. Stem cell therapy is an emerging therapeutic modality in the treatment of stroke. Its basis stems from the observation that certain parts of the adult brain are capable of regeneration (a relatively recent discovery). Neurogenesis in the adult brain has been demonstrated in the dentate nucleus of the hippocampus and the subventricular zone. In a study of patients with ischemic stroke, neurogenesis was demonstrated in the ischemic penumbra, where cells were found to preferentially localize to the vicinity of blood vessels. These findings are suggestive of poststroke compensatory neurogenesis, which may contribute to recovery after the insult. While the regenerative capacity of certain parts of the brain has been demonstrated, it is clear that this endogenous repair process is unable to overcome

the devastating damage to brain tissue that occurs after acute, severe stroke. Cell-based therapies have the potential to open up new avenues of treatment in this arena. Targets for stem cell therapy include neuroprotective approaches aimed at protecting at-risk tissue during the acute phase of stroke, as well as neuroreparative approaches which may involve direct replacement of damaged brain tissue, or alternatively promotion of the brain's endogenous repair processes.

INTRODUCTION

Stem cells (SCs) are characterized by self-renewability, i.e., the ability to divide themselves rapidly and continuously and to create new SCs and progenitors more differentiated than the mother cells. SCs show high plasticity, i.e., the ability to transform into cells from various different tissues. The plasticity can be explained by trans-differentiation (direct or indirect) and fusion. Trans-differentiation is the acquisition of the identity of a different phenotype through the expression of the gene pattern of other tissue. By fusion with a cell of another tissue, a SC can express a gene from that cell and acquire a phenotypic element of another tissue [Zhonw W 2008, Fortier LA 2005]. In the human body, adult stem cells (ASCs) maintain the tissue homeostasis. ASCs usually differentiate in a restricted range (multi-potent) of progenitors and terminal cells to replace old and damaged cells. SCs derived from early human embryos (Embryonic stem cells (ESCs)), on the other hand, are pluri-potent and can generate all committed cell types [Perra MF 2000, Pessina A 2006]. Fetal stem cells (FSCs) derive from the placenta, membranes, amniotic fluid or fetal tissues.

Today living in the 21st century, we still do not have proper treatments for many neurological diseases like Parkinson's disease, Alzheimer's disease, etc. Some light of hope for the treatment of these incurable diseases is - the stem cells. Stem cells are a special kind of cell that has the ability to divide indefinitely and have the potential to give rise to specialized cells (that is, any cell of the body). All stem cells regardless of their source have three general properties

- They are capable of dividing and renewing themselves for long periods
- They are unspecialized
- They can give rise to specialized cell types

Stem cells are capable of dividing and renewing themselves for long periods. Unlike muscle cells, blood cells, or nerve cells—which do not normally replicate themselves—stem cells may replicate many times, or proliferate. A starting population of stem cells that proliferates for many months in the laboratory can yield millions of cells. If the resulting cells continue to be unspecialized, like the parent stem cells, the cells are said to be capable of long-term self-renewal.

Broadly speaking, clinical approaches to stem cell therapy can be divided into “endogenous” and “exogenous” approaches:

- 1) The endogenous approach aims to stimulate mobilization of stem cells already present within the individual. Examples of this approach include the use of granulocyte-colony stimulating factor (G-CSF) used to mobilize hematopoietic stem

cells into the peripheral blood. G-CSF use has been shown to have both neuroprotective as well as neuroregenerative properties, [Shabitz WR 2003, Shyu WC 2004] and additionally appears to have direct effects beyond simply mobilization of stem cells.

- 2) The exogenous approach involves transplantation of the patient with stem cells delivered locally (e.g, direct intracerebral implantation) or systemically (eg, intravenous or intra-arterial) and may involve in vitro culture of cells for the expansion of cell numbers prior to administration. There is a large body of preclinical data and now mounting data from clinical trials that have utilized exogenous approaches to stem cell therapy for stroke. In this chapter, we will discuss these, and the challenges posed in translating this therapy to the bedside, in more detail. Of note, the vast majority of work has focused on ischemic rather than hemorrhagic stroke, and therefore we refer to data from ischemic stroke studies, unless stated otherwise.

STEM CELL THERAPY IN STROKE PATIENTS: THE CHALLENGES

Significant advances have been made in the field of stem cell therapy for stroke, and the potential benefits of such treatments are vast. However, several important questions remain unanswered, and translation to the bedside remains distant. The important areas of uncertainty are discussed below.

Table 1. Showing the Potency of Stem Cells

Stem Cell Type	Description	Examples
Totipotent	Each cell can develop into a new individual	Cells from early (Morula) (1-3 days) embryos
Pluripotent	Cells can vary form any (over 200) cell types	Some cells of blastocyst (5 to 14 days)
Miltipotent	Cells differentiated, but can form a number of other tissues	Fetal tissue, cord blood, and adult stem sells
Oligopotent	Cells differentiated, but can give rise to few different cells	Lymphoid and myeloid stem cells
Unipotent	Cells can give rise to their own type only	Mucles stem cells

WHICH STEM CELLS SHOULD BE USED?

Stem cells can be defined as clonogenic cells that have the capacity to self-renew and differentiate into multiple cell lineages [Weissman II 1998]. The two major types of stem cells, as classified by source, are embryonic stem cells (ESCs) and adult stem cells (Figure 2). Human ESCs are pluripotent and are isolated from 5-day-old human blastocysts. However, several factors limit the widespread use of ESCs. These include ethical concerns regarding the

use of unwanted embryos and concerns regarding tumorigenicity, specifically the risk of teratoma formation in vivo [Thomson JA 1998]. In contrast to ESCs, adult stem cells are multipotent stem cells that can be obtained from adults as well as children, including from umbilical cord blood. They are present within various organs, including the brain and bone marrow, and have the advantage of being suitable for autologous as well as allogeneic use. Of note, one disadvantage of these cells is that they have less differentiation potential than ESCs.

Figure 1. Stem cells can give rise to any cell type in the body. All stem cells, regardless of their source have three general properties: they are capable of dividing and renewing themselves for long periods; they are unspecialized; and they can give rise to specialized cell types.

A number of different types of stem cells, obtained from different sources, have been shown to improve clinical and radiological outcomes in preclinical models of stroke. The choice of cell type for clinical trial use should consider not only efficacy, but also ease of obtaining the cells, issues regarding cell culture for expansion, the need for immunosuppression and questions regarding dosage. A number of autologous and allogeneic cells have been tested in the preclinical arena. Issues specific to autologous cells include questions regarding extraction of consistent, adequate numbers of cells, as well as potency of the cells obtained (e.g., potency may fall with the age of the donor). Allogeneic cells must have the capacity for expansion to provide adequate numbers for widespread use, while ethical issues regarding the source will also need to be considered when using ESCs or fetal tissue, as previously mentioned. Cell-culturing techniques used for autologous or allogeneic cells will need to be consistent and adhere to strict safety criteria (good manufacturing practice). Long-term biological safety of any cell-based therapy is a further area of great importance. There is therefore a host of factors to consider when deciding which cell type is best to use. The different types of cells tested in preclinical studies are discussed in more detail below.

(A)

(B)

Abbreviations: UCB, umbilical cord blood; NSC, neuronal stem cell; BMMNC, bone marrow mononuclear cell; HSC, hematopoietic stem cell; MSC, mesenchymal stem cell.

Figure 2. A) Stages in using Stem cells for Therapeutic Use. B) Stem cell types used in stroke trials, and the proposed mechanisms of action.

NEURAL STEM/PROGENITOR CELLS

Neural stem cells (NSCs) have the capacity to differentiate into neurons, astrocytes, and oligodendrocytes. There are a wide variety of sources of exogenous neural stem cells, with much work being done on transplantation of embryonic and fetal-derived NSCs in experimental stroke models [Chu K 2003, and 2004 Jeong SW 2003, Kelly S 2004, Hicks AU 2009]. However, the use of such embryonic or fetal tissue is limited by ethical/legal implications, in addition to important biological questions regarding the long-term risk of teratoma formation by ESCs. The emergence of induced pluripotency, whereby skin fibroblasts from patients can be transformed into ESC-like cells, may overcome the ethical issues of using fetal or embryonic tissue in future studies, while also providing a source of autologous cells, thereby removing any questions regarding immune rejection [Takashi K 2006 and 2007, Yu J 2007]. Neural stem cells derived from the adult central nervous system are a possible alternative source of cells for transplantation. Studies have documented the isolation of NSCs from the adult rodent brain [Wachs FP 2003] as well as (more recently) the adult human brain [Nunes MC 2003]. One study demonstrated that adult NSCs derived from the subventricular zone of young adult rats could survive and migrate towards the lesion in rats with an ischemic stroke following intracisternal administration [Zheng ZG 2003]. Electron microscopy examination also suggested that the transplanted cells showed signs of neuronal differentiation.

Although possible in principle, brain biopsies for isolation of adult human NSCs and autologous transplantation poststroke is technically difficult, and no clinical trials utilizing adult NSCs have been undertaken. A number of human immortalized cell lines have been shown to improve functional outcomes after experimental stroke in rodent models. These cell lines have the advantage of providing an abundant source of cells for transplantation, available ready-prepared, at the time of a stroke. Biological safety of such cell lines, however, remains a concern in the long term. The immortalized cell line NTera-2 (NT2) was derived from a human teratocarcinoma [Andrews PW 1984]. After several weeks' exposure to retinoic acid and mitotic inhibitors, these cells differentiate into postmitotic neuron-like cells, named NT2N cells (also known as hNT neurones).²³ Terminal differentiation of these cells only occurs following transplantation into an adult brain.²⁴ The transplantation of NT2N cells into the ipsilateral striatum of ischemic rat brains improved functional recovery, with some parameters of behavioral improvement persisting for up to 6 months post-transplantation [Klepner SR 1995, Borlongan CV 1995]. No evidence of tumorigenicity was found following post-mortem examination of the rats. The CTX0E03 cell line developed by ReNeuron (Guildford, UK) is a fetally derived multipotent neural stem cell line that is conditionally immortalized with c-myc-ER, such that proliferation only occurs in the presence of the drug 4-hydroxy-tamoxifen [Stromer P 2008]. It has been shown to effect a dose-dependent improvement in sensorimotor function in rodent models of middle cerebral artery ischemic stroke when delivered intracerebrally [Taguchi A 2004].

HEMATOPOIETIC STEM/PROGENITOR CELLS

Hematopoietic stem cells (HSCs) can be obtained from bone marrow, peripheral blood, or umbilical cord blood. The advantage of such cells is that they are suitable for both autologous as well as allogeneic use, and furthermore are not associated with the ethical issues surrounding ESC or fetally derived stem cells. It is contentious whether these cells can differentiate into neuronal cells. However, preclinical studies of CD34+ cells have shown significant benefits in rodent models of stroke, with evidence of functional improvement as well as reduced infarct volume. Potential disadvantages of these cells include issues with consistency of numbers and potency of cells obtained from the bone marrow, as well as the need for ex vivo expansion of cells, when using umbilical cord blood as the source.

In one study, CD34+ cell transplantation delivered intravenously resulted in increased perilesional angiogenesis and subsequent neurogenesis in mice at 48 hours poststroke [Taguchi A 2004]. A further study investigating direct intracerebral implantation of CD34+ cells 1 week after induced stroke was also able to show evidence of neurogenesis and angiogenesis, with differentiation of transplanted cells into cells expressing markers for neurons, glial cells, and vascular endothelial cells [Shyu WC 2006].

MESENCHYMAL STEM CELLS

Mesenchymal stem cells (MSCs), also known as bone marrow stromal cells, can be obtained from bone marrow as well as such other sources as adipose tissue. As with HSCs, they are suitable for autologous as well as allogeneic use. One disadvantage of this cell type is the requirement for several weeks of cell culture to generate sufficient numbers, thereby making the use of autologous MSCs in the acute phase of stroke an unviable option.

These cells have shown significant functional benefits in rodent models of stroke in the acute as well as chronic setting (up to 1 months poststroke) and when delivered by a variety of routes (intravenous, intra-arterial and intracerebral) [Chen J 2001, Shen LH 2007, Li Y 2001]. The mechanism of improvement remains unclear, though promotion of endogenous neurogenesis, reduction of apoptosis, and induction of angiogenesis have been demonstrated in different studies [Chen J 2003].

BONE MARROW MONONUCLEAR CELLS (BMMNCs)

Mononuclear cells obtained from bone marrow contain populations of both mesenchymal and hematopoietic stem cells. They have been shown to reduce neurological deficits as well as infarct size in animal models of stroke [Brenneman 2010, Giral-di-Guimareas A 2009]. These cells are easy to obtain from bone marrow, and are suitable for autologous and allogeneic use. Transplantation with HSCs (CD34+ cells) or MSCs provides purer, more concentrated cell populations, though BMMNCs have the advantage of being easier to prepare and separate from bone marrow, making them theoretically more practical, particularly in the acute setting. As with HSCs, there are issues with obtaining consistent numbers of cells from bone marrow aspiration and questions regarding the potency of cells,

particularly in older patients [Li TS 2009]. Potential mechanisms of action include paracrine effects secreting trophic factors (such as vascular endothelial growth factor [VEGF] and stromal cell-derived factor-1), as well as possible immunomodulatory benefits [Sharma S 2010].

MECHANISM OF ACTION OF STEM CELL THERAPY

The possible mechanisms of stem cell therapy include the formation of neuronal cavity, reduced apoptosis, promotion of angiogenesis and reduced inflammation. Elucidation of potential mechanisms of action is vital to the further development of stem cell therapy techniques and ultimately translation to the bedside. There are a number of proposed mechanisms that have been investigated in preclinical stroke models (Figure 1). There is very little evidence that adult stem cells integrate into the ischemic brain and form functional neurons with adequate synaptic connections. Most studies have shown very limited numbers of engrafted cells, with functional benefits in excess of what would be expected based on the degree of engraftment. Following an ischemic stroke, neurons and glia die by a mixture of necrosis and apoptosis. Cell transplantation may elicit a neuroprotective response by rescuing the apoptotic cells, particularly in penumbral tissue. This is likely to be mediated by the secretion and upregulation of certain trophins, such as basic fibroblast growth factor, brain-derived neurotrophic factor, VEGF, glial cell-line-derived factor, and nerve growth factor. Several studies have suggested that a reduction in apoptosis in the ischemic boundary area occurs following cellular therapy that is associated with improved neurological recovery in experimental models [Kurozumi K 2005, Llado J 2004]. Immunomodulatory effects of transplanted cells may have a role in neuroprotection. Preclinical studies have shown evidence of upregulation of anti-inflammatory cytokines and attenuation of expression of proinflammatory cytokines in both ischemic and hemorrhagic stroke [Lee ST 2008, Jiang Q 2005]. If an anti-inflammatory effect is to play an important role, delivery of the cells will need to be in the early stages of the stroke. Following a stroke, regenerative strategies should be aimed at not only restoration of neural elements, but also supporting structures such as blood vessels. Angiogenesis have been demonstrated after cell transplantation with various stem cells, including NSCs, CD34⁺ cells and MSCs. Direct incorporation of the transplanted cells into new blood vessels has also been demonstrated. However, more likely mechanisms of action include the release of VEGF and also the increase in endogenous levels of other factors (such as brain-derived neurotrophic factor and fibroblast growth factor) that play a role in neovascularization [Jiang Q 2005, Cheng X 2011].

PROMOTION OF NEUROGENESIS AND OTHER ENDOGENOUS REPAIR PROCESSES BY STEM CELL THERAPY

Endogenous neurogenesis is increased per se after a stroke, likely reflecting an intrinsic host-repair mechanism [Arvidsson A 2002]. Administration of cord blood cells and mesenchymal cells have been reported to enhance endogenous neurogenesis, [Nakatomi H 2002] although whether this is likely to be functionally significant is still unclear. It is

possible that transplantation of various stem cells may amplify endogenous plasticity responses, again mediated by the secretion of trophic factors. One study suggested that intracarotid administration of MSCs facilitated host neuronal and synaptic plasticity, with increased synaptophysin expression in the ischemic penumbra [Shen LH 2006]. Furthermore, axonal sprouting from the nonischemic to the contralateral hemisphere was observed following the intravenous administration of human cord blood cells [Xia J 2005].

Other stem/progenitor cells are also increased following cerebral ischemia. Under physiological conditions, a relatively small pool of CD34+ stem/progenitor cells circulates in the peripheral blood. An Ischemic stroke is known to increase levels of CD34+ cells (mobilized from the bone marrow) in the peripheral blood [Paczkowska E 2005]. In addition, there is evidence that increased CD34+ mobilisation into the peripheral blood in patients with acute ischemic stroke correlates with neurological recovery, with high counts associated with better recovery [Dunac A 2007]. Treatment with G-CSF, for example, which mobilizes CD34+ cells into the peripheral circulation, may potentially enhance this endogenous repair mechanism.

BENEFITS OF STEM CELL THERAPY TO PATIENTS

A crucial question for upcoming clinical trials is which patients will benefit from stem cell therapy. The pathological type and anatomical location of the stroke are important issues, which are discussed in more detail below. In addition, demographic differences, in particular differences in age and gender, are also likely to affect how patients respond to treatment.⁵⁴ The vast majority of preclinical work has been conducted on young, previously healthy, male animals. Elderly patients, who represent the largest subset of stroke victims, may not derive the same benefit as that seen in such animal studies. As stated previously, the majority of preclinical work has focused on ischemic rather than hemorrhagic strokes. In view of this, the ongoing and completed clinical trials have almost exclusively concentrated on ischemic stroke patients. Of the published clinical trials to date, only one has included any patients with hemorrhagic strokes [Kondziolka D 2005].

Within the ischemic stroke subgroup, the majority of preclinical evidence for benefit has been obtained from animal models with predominantly striatal infarcts. A smaller number of trials have investigated cortical models of stroke, with mixed results [Hicks AU 2008]. Cortical strokes are associated with larger, more damaging infarcts, and it may be that these are too large to affect any repair. A direct comparison between subcortical and cortical infarcts in addition to various doses of cells would be useful in order to optimize patient selection. For example, one preclinical study that compared anatomical location found the benefit of stem cell therapy to be more pronounced in striatal infarcts, rather than larger cortical lesions [Smith EJ 2012]. Further issues to consider when designing clinical trials are stability of patients and associated comorbidities. Patients with larger strokes are commonly medically unwell due to multiple reasons (eg, aspiration pneumonia, cardiac arrhythmias), which could preclude them from entry into acute trials despite being eligible. Furthermore, multiple comorbidities are also likely to affect the response of the patient to stem cell therapy.

OPTIMAL TIMING FOR TREATMENT

Preclinical studies have shown benefits of stem cell therapy in both acute and chronic models of stroke. Decisions regarding the ideal timing need to take into account the likely mechanism of action. A neuroprotective mechanism would require acute delivery, although graft survival may be affected by the damaging effects of ischemia and reperfusion, mediated via excitotoxic neurotransmitters, free radicals, and other inflammatory mediators [Mitsios N 2006]. If the aim is to enhance endogenous repair mechanisms and inhibit neuronal apoptosis, then acute or subacute delivery would be desirable, as these processes occur predominantly in the first few weeks postischemia [Hayashi T 2003]. A neuroreparative approach aiming for direct replacement of damaged tissue with new neuronal circuitry (using intracerebral transplantation), would benefit from a later timescale, once neuroinflammation has subsided. Such a strategy would be looking at treatment delivered weeks to months after the stroke, in keeping with ongoing host plasticity during that time.

Future studies will need to address questions regarding timing, with direct comparisons between acute and chronic delivery. One animal study demonstrated significant neurological improvements with intravenous injection of BMMNCs at 24 and 72 hours, poststroke but showed no improvement in animals treated at 7 days poststroke [Yang B 2011]. Other studies comparing acute to chronic delivery of cells have shown conflicting results, though there were important differences between these trials in terms of the cells used, animal model, and exact timing of transplantation. [Grabowski M 1994, Darsalia V 2011] Such comparative data is sparse in the preclinical arena and sorely lacking in the clinical arena, and at present the optimal timing of treatment is yet to be determined.

DELIVERY ROUTE OF STEM CELLS

Studies in the preclinical and clinical settings have used a variety of different routes of stem cell delivery, illustrating the point that the best delivery method remains unclear. Benefits have been seen using direct intracerebral implantation as well as systemic delivery using the intravenous and intra-arterial routes. Intracerebral implantation allows direct delivery of cells to the affected site, but is invasive and may present issues of disrupting the underlying brain tissue. Use of a general anesthetic for intracerebral delivery, particularly in the acute stroke patient, is problematic, though alternatively a local anesthetic can be used. The intravenous route is the safest, easiest route of delivery, though there are issues regarding accumulation of cells in nontarget organs, with only a small proportion reaching the brain [Fisher UM 2009]. The size of the cells used is important in this regard. The intra-arterial route allows more direct delivery of cells, allowing better first-pass delivery while being less invasive than direct surgical implantation.

Decisions regarding the route of delivery will need to take into account issues regarding the practicality and safety, as well as cell type/dosage and proposed mechanism of action. The best route of delivery is yet to be determined, and there is a paucity of preclinical data comparing the different available delivery methods. One study of ischemic stroke in rats compared intravenous to intra-arterial delivery of neural progenitor cells. Their data showed a superior cell delivery to the ischemic hemisphere, with the intra-arterial route [Lappalainen

RS 2008]. However, as mentioned previously, all three modes of delivery have clearly shown benefits in different preclinical studies, which raise the question: is it necessary for cells to enter the brain to have their beneficial effect? More well-designed trials are needed to directly compare different routes of delivery using standardized criteria, in order to help answer these vital questions.

How Can Transplanted Cells Be Tracked?

Tracking of cells is paramount to improving our understanding of cell migration and mechanisms of action. Currently there is no ideal method of doing this, with the techniques available being suboptimal for a number of reasons.

One commonly employed tracking method in preclinical studies is cell labeling with superparamagnetic iron oxide particles, which allows the anatomical location of transplanted cells to be determined using magnetic resonance imaging (MRI) [Bulte JW 2002]. Other examples of imaging modalities used to track labeled cells include positron emission tomography (PET), bioluminescence imaging (BLI), and single-photon-emission computed tomography (SPECT) [Love Z 2007]. One drawback of many cell-labeling techniques is the difficulty tracing the labeled cells when they divide, either due to failure of uptake of the label or the presence of a weaker signal in the new cells. In addition, if the cell dies and is phagocytosed by macrophages, any signal received will be misleading [MrColgan P 2011]. BLI overcomes this issue, as it picks up luminescence signals emitted from living cells. However, one of the concerns with BLI is poor spatial resolution, an important drawback of this modality [Bliss T 2010].

To date, only one clinical trial of stem cell therapy in stroke patients has investigated the role of tracking the transplanted cells. A study of BMMNCs labelled with technetium-99m (^{99m}Tc) looked at cell homing and uptake using whole-body scintigraphy and SPECT scans [Barbossa LM 2010]. They confirmed the presence of cells in the brain at 2 hours, as well as distributed to the liver, lungs, spleen, kidneys, and bladder. Furthermore, preferential accumulation of radioactivity was seen in the ipsilateral affected hemisphere (compared to the contralateral hemisphere) in all patients at 2 hours postinfusion. In addition to tracking cells, imaging modalities are also required to evaluate the functional outcome of transplanted cells. Diffusion-weighted MR studies can be used to assess for neovascularization, PET scanning to assess metabolic changes, diffusion-tensor imaging to assess fiber-tract integrity, and functional MRI to assess neuroplasticity. It is likely, therefore, that a combination of imaging modalities will eventually be required to give a better overall assessment of the fate of transplanted cells, in order to further the understanding of their mechanisms of action.

Stem Cell Therapy in Stroke Patients: Clinical Trials

Clinical trials of stem cell therapy in stroke patients are still in their infancy. There have been a number of recent phase I/II trials, primarily investigating the role in ischemic stroke patients. However, these trials have not clearly defined the best cell type, route of delivery, or timing of therapy, and more coordinated research is needed to better answer these uncertainties.

The majority of preclinical work has focused on treatment in the acute or subacute phases of stroke. In contrast, all the early clinical trials have concentrated on chronic stroke patients. There is certainly preclinical evidence pointing to benefit in the chronic subgroup. In addition, patients are more stable and chronic delivery occurs well after the acute inflammatory response has subsided. There are now an emerging number of acute human trials that have also been completed. Reasons for acute delivery of cells have been discussed previously. It is important to note that the pathophysiological processes and proposed mechanisms of action in the acute phase are quite different to the chronic phase of stroke, and it is not possible to extrapolate data gleaned from one setting to the other. Future studies will need to address questions regarding the ideal timing of transplantation.

The currently available clinical trial data utilizing human stem cells will be discussed further, as well as a discussion on ongoing trials, of which there are now several scattered across different centers worldwide.

CHRONIC STROKE TRIALS

NT2N Cells

NT2N were the first human cells to be tested in stroke clinical trials. A phase I trial examined the safety of direct stereotactic transplantation of cells into patients with basal ganglia stroke that had occurred 6 months to 6 years previously [Kondziolka D 200]. Twelve patients with stable motor deficits were treated, along with an immunosuppressive regimen of cyclosporine-A due to the allogeneic nature of the treatment. Two doses of cells were used: 2×10^6 and 6×10^6 cells. There was a trend towards improved functional outcomes in the four patients who received the higher dose of cells. Autopsy on one patient, who died of myocardial infarction 27 months post-transplantation, showed apparent survival of NT2N cells in the brain. Furthermore, PET scans at 6 months post-transplantation showed increased metabolic activity at the site of infarct in six patients [Nelson PT 2002]. This initial safety trial led to a phase II study assessing the effect of NT2N cell transplantation in 18 patients with a basal ganglia stroke between 1 and 6 years previously. Stereotactic cellular transplantation plus two months of rehabilitation ($n = 14$) was compared to control patients who received rehabilitation alone ($n = 4$). Six of the 14 patients who received a transplant appeared to show improvement on a standardized stroke scale, but this was not statistically significant against control patients. Of note, this trial included ischemic ($n = 9$) and hemorrhagic strokes ($n = 9$).

Mesenchymal Stem Cells

The extensive preclinical work on MSCs described previously led to a phase I/II clinical trial using autologous culture-expanded MSCs in patients with ischemic middle cerebral artery (MCA)- territory stroke.⁷⁵ Thirty patients with established stroke (1 month postinfarct) were randomized to receive MSCs by the intravenous route ($n = 5$) or no MSCs ($n = 15$). Cells were extracted by bone marrow aspiration and culture-expanded prior to infusion. There

was no cell-related toxicity related to the MSC administration, and the authors suggested that functional improvement may have been better in the transplanted group compared with the control group, although this was not statistically significant. There were no significant differences between the two groups in relation to changes in infarct volume at 1-year follow-up. Following on from this study, the same group conducted a trial looking at the long-term (5-year) effects of MSC transplantation in patients with severe MCA-territory stroke [Lee JS 2010]. Sixteen patients (versus 36 controls) were treated with intravenous delivered, autologous, culture-expanded MSCs. There was no difference in adverse events between the two groups. Functional outcome appeared to be better in the treated group, with a significantly increased proportion of patients with a modified Rankin score of 0–3, compared to the controls.

A further trial of autologous MSCs administered in ischemic stroke patients, within 6 months of their event, was recently reported [Honmou O 2011]. Cells were delivered intravenously 36–133 days poststroke in an open-label study of 12 patients. MSCs were serum-expanded prior to infusion. The treatment was shown to be safe and feasible, with no significant adverse events. Furthermore, mean infarct volume as assessed by MRI was reduced by .20% at 1 week postinfusion. Of note, the culturing conditions and media were different between the two MSC trials described above.

Bone Marrow Mononuclear Cells

Two trials utilizing BMMNCs have been reported in chronic stroke patients. One open-label study treated six male patients with the MCA-territory ischemic stroke within 90 days of the event.⁷⁸ Autologous BMMNCs were isolated after bone marrow aspiration. The cells were then delivered intra-arterially, with a proportion of these labeled with ^{99m}Tc. There were no treatment-related adverse events up to 6 months follow-up. Evidence was seen of cell migration in the brain at 2 hours postinfusion in all six patients, though at 24 hours this number had dropped to two patients [Barbosa LM 2010]. All patients showed improvements in their National Institutes of Health Stroke Scale scores by 6 months. In a separate study, autologous bone marrow stem cells obtained by bone marrow aspiration were transplanted stereotactically in five patients with established stroke [Saurez C 2009]. The procedure was well tolerated, with no adverse events up to 1 year follow-up.

Ongoing Chronic Trials

There are at least ten other ongoing or completed trials in chronic (4 weeks post event) stroke patients that are yet to report. Details of these unreported trials are listed in Table 5.2. A number of different cell types at different time points and via different methods of delivery are being tested. These include allogeneic cells, such as the CTX0E03 neural stem cell line, which has been discussed previously.

Such commercially developed cell lines, if shown to be beneficial, are an exciting prospect owing to the ability to develop them for “off the shelf” use, available ready-prepared at the time of a stroke. The results of these various trials are awaited with interest, though it is clear to see that meaningful comparisons between the different trials will be difficult to make,

and how far these trials will go towards answering the outstanding questions in this field is difficult to say.

ACUTE STROKE TRIALS

Bone Marrow Mononuclear Cells

There are currently three published trials of stem cell therapy in acute stroke patients. All three trials utilized BMMNCs and were able to demonstrate safety and feasibility in the treated subjects. One study treated ischemic stroke (MCA territory) patients at 24–72 hours post event with intravenously delivered cells [Friedrich M 2012]. Ten patients were treated in an open-label study, with no evidence of study-related serious adverse events up to 6 months follow-up. All patients had shifted down by at least 1 point on the modified Rankin Scale (mRS) at 6 months compared to at day 7. The second study (also open-label) treated 20 patients with MCA-territory ischemic stroke at 3–7 days post event, with the cells delivered intra-arterially [Friedrich M 2010]. There were no procedure-related adverse events reported up to 6 months follow-up. A good outcome (defined as an mRS of #2) was seen in eight of the 20 patients at 90 days. The third, most recently published trial treated ten patients with BMMNCs delivered intra-arterially at 5–9 days after stroke [Monichie F 2012]. This was a single-blind, controlled study (ten consecutive controls; nonrandomized). Two of the treated patients had isolated partial seizures at 3 months. There were no significant differences in neurological outcome between the two groups at final 180-day follow-up. None of these trials were powered to demonstrate efficacy.

Ongoing Acute/Subacute Trials

A further six acute/subacute trials (4 weeks poststroke) are ongoing or yet to report (Table 5.3). As with the chronic stroke trials, these are utilizing a variety of different cell types, including BMMNCs, CD34⁺ cells, and MSCs, as well as commercially developed stem cell lines. We have investigated the use of intra-arterially delivered CD34⁺ cells in patients with severe MCA-territory ischemic stroke, recruited within 7 days of the event (ClinicalTrials.gov identifier NCT00535197). To date, no trial has reported on the effects of immunoselected CD34⁺ cells for acute or chronic ischemic stroke. Such cells have been shown to improve functional outcome and infarct size in preclinical models. Furthermore, a recently published trial of BMMNC treatment of acute ischemic stroke showed a trend towards a positive correlation between number of CD34⁺ cells injected and functional outcome at 1 month [Monichie F 2012]. We have demonstrated safety and feasibility in our patient cohort, as well as improvements in clinical scores and functional status at 6-month follow-up (unpublished data). Of the other ongoing studies, one is investigating the use of MSCs in hemorrhagic as well as ischemic strokes. This will be of interest, as the use of stem cells for hemorrhagic stroke has not been well investigated in the clinical arena. It must be borne in mind however, that the underlying pathophysiological processes at play and therefore the mechanisms of recovery are quite different between these subtypes of stroke. The completed results of these various trials are eagerly awaited.

Table 2. Summary of ongoing or completed (but unreported) chronic stroke trials

Cell type	Study design	Expected no of patients	Timing of delivery post stroke	Route of delivery	Clinical trial identifier	Trial status
Chronic trials (4 weeks post event)						
CTX0E03 neural stem cells	PI, NR-OL	12	6 months–5 years	IC	NCT01151124	Recruiting
MSCs	PII, R-OL	30	,6 weeks	IV	NCT00875654	Recruiting
CD34+	PII, R-OL	30	6–60 months	IC	NCT00950521	Complete
CD34+	PI, NR-OL	6	6–60 months	IC	NCT01438593	Not yet recruiting
CD34+	PI, R-OL	40	,1 year	IA	NCT01518231	Recruiting
MSCs, EPCs	PI/II, R-DB	90	5 weeks	IV	NCT01468064	Recruiting
MSCs	PII, R-OL	50	1 week–2 months	IV	NCT01461720	Recruiting
MSCs	PI/II, NR-OL	35	.6 months	IV	NCT01297413	Recruiting
SB623	PI/II, NR-OL	18	6–36 months	Unclear	NCT01287936	Recruiting
OECs	PI, R-SB	6	6 months–5 years	IC	NCT01327768	Recruiting

Note: CTX0E03 and SB623 are commercially developed stem cell lines.

Abbreviations: BMMNC, bone marrow mononuclear cells; MSCs, mesenchymal stem cells; OECs, olfactory ensheathing cells; EPCs, endothelial progenitor cells; NR, nonrandomized; OL, open-label; PI and II, phase I and II trials; R, randomized; SB, single-blind; DB, double-blind; IV, intravenous; IA, intra-arterial; IC, intracerebral.

THE FUTURE

Routine use of stem cells at the bedside for stroke patients is an exciting prospect, though realistically remains a long way off. The future may well see the availability of “off-the shelf” stem cell products available for immediate use. Perhaps patients will receive individually tailored stem cell products, engineered to secrete specific trophic factors, to suit their specific subtype and duration of stroke. There is clearly a long way to go in both preclinical and clinical research, and long-term biosafety measures will be an essential consideration in this regard.

A number of clinical trials have now begun to demonstrate the safety and feasibility of different approaches to stem cell therapy. However, there are a large number of unanswered questions that remain. The great variation in the stem cell trials completed to date means that it is difficult to make any meaningful comparisons between them. Future clinical trials will need to start trying to address the important outstanding questions. It is imperative that trials are therefore designed with this in mind. Careful planning and collaborative work need to take place in order to maximize the likelihood of getting a useful answer from these studies. This includes such considerations as incorporation of a dose-escalation design and comparisons between different methods of delivery as well as different time points for delivery. The Stroke Therapy Academic Industry Roundtable (STAIR) II meeting elucidated the important considerations when designing future phase IIb studies. Many of these recommendations are particularly relevant to the field of stem cell research (see Figure 2; important factors highlighted). They emphasized that “lack of establishing the optimal dose, duration of therapy, and time window may have contributed to the failure of neuroprotection trials.” Therefore, refinement and identification of the target population is essential. In addition, narrowing selection criteria in phase IIb studies to target patients more likely to respond based on clinical and imaging characteristics may optimize the chances of detecting a biologically relevant drug effect (STAIR IV recommendations). Subsequent to these publications, the Stem Cell Therapies as an Emerging Paradigm in Stroke (STEPS) meeting sought to develop a framework specifically to help guide design of future preclinical and clinical studies in the field of cell-based therapies [STEPS 2009]. These recommendations from experts from the preclinical and clinical arenas should be carefully borne in mind before commencing any future trials.

In conclusion, there have been significant advances made in the field of stem cell research over the last two decades, with evidence of significant benefits in both acute and chronic animal models of stroke. Translation to clinical practice, however, remains a long way off. A number of trials are under way, though future work will need to concentrate on overcoming the still-significant challenges standing in the way of this becoming a realistic treatment option for the future.

Table 3. Summary of ongoing or completed (but unreported) acute/subacute stroke trials

Cell type	Study design	Expected no of patients	Timing of delivery poststroke	Route of delivery	Clinical trial identifier	Trial status
Acute and subacute trials (,4 weeks postevent)						
BMMNC	PII, R-OL	120	7–30 days	IV	NCT01501773	Complete
MSCs	PII, NR-OL	120	7–14 days (infarct)or 10–21 days (ICH)	IV, then intrathecal 7 days later	NCT01389453	Recruiting
CD34+	PI/II, NR-OL	10	7 days	IA	NCT00535197	Recruiting
MSCs	PI/II, R-DB	78	,10 days	IV	NCT01091701	Not yet recruiting
MultiStem	PII, R-DB	140	1–2 days	IV	NCT01436487	Recruiting
ALD-401	PI/II, R-DB	100	13–19 days	IA	NCT01273337	Recruiting

Note: MultiStem and ALD-401 are commercially developed stem cell lines.

Abbreviations: BMMNC, bone marrow mononuclear cells; MSCs, mesenchymal stem cells; OECs, olfactory ensheathing cells; EPCs, endothelial progenitor cells; NR, nonrandomized; OL, open-label; PI and II, phase I and II trials; R, randomized; SB, single-blind; DB, double-blind; IV, intravenous; IA, intra-arterial; IC, intracerebral; ICH, intracerebral hemorrhage.

**Table 4. Stroke Therapy Academic Industry Roundtable (STAIR)
II recommendations**

Considerations for designing phase IIb stroke trials
• Route of administration
• Dose range
• Duration of treatment
• Time from stroke onset to initiation of treatment (a key variable)
• Pharmacokinetic profile
• Side effects and their frequency (with attention to side-effect management)
• Interactions with other commonly used medications
• Drug distribution to the proposed site of action
• Refinement and identification of the target population (e.g, drugs without preclinical evidence of activity in white-matter ischemia should not be studied in patients with subcortical stroke or even large cortical events with attendant subcortical injury)
• Obtain evidential measurement of therapeutic activity by evaluation of clinical and/or surrogate markers (hints of potential effectiveness)

SOURCES OF TRANSPLANT CELLS

Stem cells must possess two characteristics: they must be able to replicate and they must have the capacity for differentiation into multiple cell lines [Preston SL 2003]. Stem cells vary in their degree of potential for differentiation. Totipotent cells can form the embryo, as well as any cell line. Pluripotent cells cannot form an embryo, but can differentiate into cells of multiple different tissue cell lines. Multipotent cells can only produce a limited set of cell lines, appropriate for a given tissue environment. Unipotent cells can only generate one cell type. Thus, fetal tissue can possibly yield pluripotent stem cells and certainly generate organ-specific multipotent stem cells. Of course, the use of human fetal tissue is controversial for ethical reasons and limited (in the USA) by recent legislative restrictions. Other potential sources for stem cells exist. Multipotent stem cells have been identified within adult tissue, including brain, although not in sufficient numbers to be reasonably extracted for clinical use [Gu W 2000]. In some organs, notably the bone marrow, multipotent cells have shown a capacity to “change their minds” and transdifferentiate into lineages of other organs, including neural cells [Sanchez Ramos J 2000, Woodbery D 2000]. There is evidence that human umbilical cord blood cells (HUBCs) may also manifest transdifferentiation [Sanchez Ramos JR 2001]. Finally, tumor cell lines occasionally yield lines of immortal, organ-specific, multipotent stem cells. An example of a tumor cell line that may prove useful in neurotransplantation is the Ntera 2/cl.D12 (NTs) human embryonic carcinoma-derived cell line [Kleppner SR 1995]. These cells replicate and differentiate into human neuronal cells [Trojanowaski JQ 1993]. Thus, NTs have the characteristics of multipotent neural stem cells. When transplanted, these neuronal cells survive, extend processes, express neurotransmitters, form functional synapses, and integrate with the host. The final cells appear virtually indistinguishable from terminally differentiated, postmitotic neurons. The cells are capable of differentiation to express different neuronal markers characteristic of mature neurons. Their neuronal phenotype makes them a promising candidate for replacement in central nervous system disorders, as a virtually unlimited supply of pure, postmitotic, terminally differentiated human neuronal cells.

MULTIPOTENT CELL TRANSPLANTS IN ANIMAL MODELS OF STROKE

In 1998, Borlongan et al. showed that transplants of LBS-neurons could reverse the deficits caused by a stroke (Borlongan CV 1998). They used a rat model of permanent focal ischemia. At 1 month postischemia surgery, they selected all rats that showed significant behavioral deficits and randomized this group to receive transplantation either of fetal rodent striatal cells ($n = 8$) or human embryonic carcinoma-derived (hNT) neurons ($n = 14$). They had an existing set of 22 control rats that received transplants of either cerebellar cell or cell medium. They tested all animals at 1, 2, 3, and 6 months after surgery, having noted previously that ischemic animals continue to display significant deficits for >3 months postischemia. They used the passive avoidance test (the same test used to identify rats with significant deficits poststroke) and the elevated body swing test (EBST), a measure of motor asymmetry. The rats who received either striatal fetal cells or hNT neurons significantly outperformed the controls; rats receiving hNT had a significantly earlier recovery of

behavioral deficits compared to those who received the striatal fetal cells. Similarly, rats who received hNT neurons recovered motor symmetry significantly faster than those receiving striatal fetal cells, while both of these groups significantly outperformed the controls. Immunohistochemical staining done on treatment rats showed that there was survival of the grafted cells after 6 months.

CELL TRANSPLANTS IN HUMAN STROKE

The transplantation of hNT neurons into the brains of humans with stroke has now undergone Phase I and Phase II trials, with promising results. The first clinical study of transplantation of the immortalized line of hNT cells into human stroke victims was conducted at the University of Pittsburgh. The goal was to demonstrate the safety and feasibility of the neuronal cell implantation procedure. The study was an open-label trial with observer-blinded neurologic evaluation of patients with stroke who received stereotactic implants of human neuronal cells. Patients with basal ganglia infarcts and stable motor deficits were enrolled. They had to have had strokes between 6 months and 6 years prior to transplantation. The mean time since onset of the stroke was actually 27 months (range 7 to 55). Cells were delivered stereotactically via three 20- μ l injections along a single trajectory through the infarct. The first four patients received 2 million cells via single-pass injections into the area of infarction. The next eight patients were randomized to receive either 2 or 6 million cells (three separate stereotactic trajectories with three injections each around the stroke). Because of concerns for cell rejection, the patients were given intravenous methylprednisolone during the procedure, followed by cyclosporine-A administration beginning 1 week before surgery and for 8 weeks following. Patients were evaluated for safety and efficacy at ten intervals over the 52 weeks following surgery. Disability was assessed using the National Institutes of Health Stroke Scale (NIHSS), European Stroke Scale (ESS), and Barthel Index (BI). Positron emission tomography using fluorodeoxyglucose (FDG-PET) and magnetic resonance imaging (MRI) scans were obtained at baseline; MRI was repeated at weeks 4 and 24, while PET was repeated at weeks 24 and 52. The goals of demonstrating safety were met, with no adverse events related to implantation. One patient developed renal insufficiency attributed to the cyclosporine-A. One patient, whose infarct involved temporal lobe cortical tissue, had a generalized seizure 6 months after the surgery and was treated successfully with anticonvulsant medication. One patient had a subsequent stroke, remote from the site of neuronal transplantation, 6 months after the surgery. No malignancies, deaths, or cell-related adverse events occurred in the follow-up period. Although the study was not designed as an efficacy study, the functional outcomes suggested clinical benefit. The ESS, which had been stable between the preoperative evaluation and the day of surgery, improved in 6 of the 12 patients, remained unchanged in 3, and deteriorated in 3, compared with baseline scores. The mean improvement in ESS from baseline to week 24 was 2.9 points, achieving significance ($p = 0.046$). Motor improvement accounted for much of the clinical improvement in the ESS in the patients enrolled in this first study. The NIHSS seemed to improve overall in the group, without achieving significance: eight patients had improved, one was unchanged, and three deteriorated at the 24-week follow-up. The BI did not change significantly. Serial MRI scans showed no changes in the brain after the surgery

when compared with baseline. The serial PET scans, however, manifested differences between the baseline and follow-up studies done 6 months later. There was an increase in $\geq 15\%$ in the relative uptake of FDG within the transplant site, in 6 of 11 patients. This increased metabolic activity suggests the return of viable neurons to the areas of infarction. While an inflammatory response could produce such findings, there was no sign of inflammation on serial MRI. The suggestion of cell survival in the serial PET studies was corroborated by some pathological data. One of the patients, a 71-year-old man, died of a presumed myocardial infarction 27 months following the transplantation surgery. He was one of the patients who demonstrated no motor recovery. Histochemical stains of his brain demonstrated a population of neurons at the graft site. Many of these were NF protein immunoreactive, suggesting that they were nNT neurons. This was confirmed with a special single chromosome 21-specific probe (specific for hNT neurons) that detected multiple signals in nuclei within the area of the graft. Therefore, in the Phase I study, transplantation of the hNT neurons into areas of stroke was shown to be both safe and feasible. The transplant cells survived, and there was even a suggestion of clinical benefit. A Phase II dose-response trial was undertaken at two centers (University of Pittsburgh and Stanford University). Patients were randomized. The first seven of these received 5 million cells along five trajectories with five injections each (i.e., one million cells per trajectory), while another seven patients received 10 million cells, along five trajectories and with five injections each. There were four control patients. All patients received cyclosporine for 6 months as well as focused stroke rehabilitation. The primary outcome was the motor ESS at 6 months. NIHSS, ESS, and MRI were done on routine follow-up. The safety results of the Phase II trial were similar to those of Phase I, with no major medical complications of the procedure and no lasting effects due to implantation or cyclosporine administration. One patient experienced a syncopal episode, 1 month following surgery. One patient experienced a seizure 1 day after surgery. One patient, who was on aspirin and clopidogrel combination therapy, underwent surgical drainage of a chronic subdural hematoma, 1 month following transplant. Two of the four control patients experienced improvements in their motor ESS scores after 6 months of physical therapy. The range of change on this scale was -0.5 to $+3.5$ points. Of the transplant group, 8 of the 14 improved after 6 months, and the range was -5.5 to $+14.5$. Overall, the transplant group had a statistically insignificant improvement in motor ESS over the control group ($p = 0.148$). However, the relatively large degree of improvement of some of the transplant patients was notable. Unexpected improvements were also noted in some of the secondary outcome measurements. For example, there seemed to be a trend toward improvement in the treatment group with respect to hand and wrist movement. Interestingly, there were significant improvements in certain neuropsychological measurements, such as visuospatial construction and retention, and nonverbal memory, in the treatment group compared with the controls. These results were recently published [Kondziolka D 2005, Stillely CS 2004].

From these first two trials, it is inferred that stereotactic cell implantation of immortalized multipotent neural stem cells, derived from a tumor cell line, is relatively safe and devoid of delayed cell-related adverse effects; the transplanted cells survive *in vivo*; and some patients that received cell transplants showed motor and cognitive improvements. Future trials using this cell line will have to address optimal patient selection, timing of surgery, number of cells needed, optimal implant location, and the need for immunosuppression.

POSSIBLE MECHANISMS

It remains unclear exactly how hNT neuron transplants exert their effects in animal stroke models and their possible effects in humans with stroke. There is suggestive evidence that the transplanted cells do survive. It remains to be proven whether they also integrate into the existing neural network that surrounds them, although the surprising improvement in cognition that was observed in some of the transplant patients, if there must also be other mechanisms involved. The improvements noted in the bone marrow stromal cell [Bang Oy 2005] pilot trial and in the HUBC animal models [Chen A 2001] occurred too soon to be attributable to neuronal integration. Perhaps, the transplanted cells induced a host response, such as the secretion of neurotrophic factors, which independently promoted recovery. BMSCs are known to secrete interleukins (IL)-6, IL-7, IL-8, IL-12, IL-14, IL-15, along with macrophage stimulating factor, Flt-3 ligand, and stem cell factor [Eaves CJ 1991]. These cytokines have been identified as promoters of growth and survival of mouse hippocampal neuron progenitor cells [Mehler MF 1993]. BMSCs also release neurotransmitters which can supplement for lost neurons after ischemia. It is therefore possible that these or other trophic factors could perhaps stimulate synaptic sprouting in damaged brain tissue.

CONCLUSION

Stroke is a major cause of disability, and a repair strategy needs to be developed. Cell therapies have the potential for providing a means of repairing brain tissue that has been permanently injured by stroke. There are several sources of neuronal progenitor cells that are under investigation. In animal models, it has been successfully shown that fetal cell transplants are able to survive and convey functional recovery. BMSCs and HUBCs seem to be able to transdifferentiate into neuronal cells and survive in the brains of animals with stroke. On the other hand, further research is required to determine the functional significance of this mode of transplantation. Implanted tumor-derived neuronal progenitor cells (hNT neurons) survive and convey functional improvement in animals. There is promising preliminary evidence that the same holds true for humans. Once a source of neuronal progenitor cells can be found that can consistently differentiate into viable neuronal cells and then survive within stroke-injured brain tissue, further research will then be able to refine the process. Future research would then focus on determining the ideal timing of transplantation, selection of the best size and location of the cellular implant, and possibly even optimizing the cellular environment by controlling local trophic factor concentrations. The goal is to replace lost neurons in a self-sustainable tissue milieu, and reintegrate the replacement cells into existing neural networks, in order to ultimately restore functions that have been lost.

Chapter 16

AN INTRODUCTION TO CEREBROVASCULAR DISEASES

Manzoor A Mir*

¹Department of Bioresources, Faculty of Biological Sciences, University of Kashmir, Srinagar-190006, India

ABSTRACT

Cerebrovascular disease [CVD] is the most common life threatening neurological condition, a major contributor to morbidity, functional disability and mortality worldwide. According to the recent epidemiological data, it is expected that, till 2020, coronary artery disease and cerebral hemorrhage will be still the first and second causes of death of human beings, even though the order of the death causes due to human diseases would be changed significantly. CVD are a heterogeneous group of disorders such as stroke, vascular cognitive impairment, and even certain migraine subtypes with a variable natural history. Neurovascular disease has a wide range of phenotypes involving multiple cell types of the brain, the blood brain barrier [BBB], and interaction with the peripheral systemic circulation. Unlike cardiovascular disease, which largely involves in situ vascular thrombosis, neurovascular disease can induce focal injury with thrombotic [involving larger and small vessels], embolic [from cardiac source or periphery], hemorrhagic [intracerebral and subarachnoid], inflammatory, and traumatic mechanisms, to name only a few. It can result in global ischemic injury from lack of perfusion, such as from sudden cardiac arrest. Outcome depends on many factors, including the underlying pathophysiology, collateral cerebral circulation, and concurrent illness, especially heart disease. About 80% of all cerebrovascular events are ischemic in origin, and most are associated with atherosclerotic disease. Despite various advances in the understanding of the diseases, pharmacological treatment by conventional medicine has not obtained satisfactory results. However, recent studies suggest that natural products and traditional herbal medicine are a potential candidate for the preventative treatment of the disorders. Therefore, the application of bioactives/traditional herbal medicine in prevention and treatment of cerebrovascular diseases is of great significance. A history of

* Corresponding author: Dr Manzoor Ahmad Mir Department of Bioresources, Faculty of Biological Sciences, University of Kashmir Srinagar-190006, India Email: mirmanzoor110@gmail.com and drmanzoor@kashmiruniversity.ac.in Tel. +919797110211.

cerebrovascular disease is important because specific therapy may be indicated to prevent further events, and because the history of cerebrovascular disease may be a "marker" for other underlying disease, especially coronary artery disease. This chapter will discuss in detail the different types of CVD, their risk factors and other parameters of CVDs.

INTRODUCTION TO Cerebrovascular Diseases

Worldwide stroke and other cerebrovascular diseases [CVD] are a leading cause of physical disability. They are the second commonest cause of mortality [accounting for 10.8% of all deaths; [WHO, 2011] and the primary reason for admission in a large proportion of hospital inpatients [1]. The World Health Organization defines stroke as a rapidly developing focal [or global] brain dysfunction of vascular origin lasting more than 24 h, thus encompassing ischaemic stroke, intracerebral haemorrhage, subarachnoid haemorrhage and cerebral venous sinus thrombosis [2]. CVD is highest in the elderly and the morbidity and costs associated with age-related disorders such as these are likely to continue to mount with the pattern of extended life expectancy observed in Western populations [3]. There are around 700,000 new and recurrent strokes per year in the US, with costs related to stroke estimated to be over \$60 billion in 2007 [4]. Cerebrovascular disease remains a devastating and highly morbid disease and the third leading cause of death after heart diseases and cancer in developed countries. The economic burden of stroke is tremendous, both because of the direct costs of medical care, medications, and rehabilitation, and indirect costs such as lost time at work and caregiver burden. Cerebrovascular disease is caused by one of several pathological processes involving the blood vessel of the brain. The process may be intrinsic to the vessel as in atherosclerosis, lipophyalinosis, inflammation amyloid deposition arterial dissection, developmental malformation, aneurysmal dilation, or venous thrombosis; originate remotely, as occurs when an embolus from the heart or extracranial circulation lodge in an intracranial vessel; result from decreased perfusion pressure or increased blood viscosity with inadequate cerebral blood flow; or result from rupture of a vessel in the subarachnoid space or intracerebral tissue[5]. Cerebrovascular diseases are a heterogeneous group of disorders with a variable natural history. Outcome depends on many factors, including the underlying pathophysiology, collateral cerebral circulation, and concurrent illness, especially heart disease [6].

The risk of an ischemic event increases with age and is correlated with both systolic and diastolic blood pressure, diabetes, and a history of ischemic heart disease or previous stroke. All epidemiologic studies have identified hypertension as the most important risk factor for CVD. Correlation with cigarette smoking and hyperlipoproteinemia is less conclusive. A neurologic symptom or symptom complex caused by cerebral ischemia or hemorrhage is commonly called a cerebrovascular accident (CVA), or stroke. CVDs are a very diverse group of disorders that are further classified according to etiology, location, and duration of symptoms. CVDs are subdivided into ischemic events and cerebral hemorrhages, with many etiologies for each. Ischemic events are further classified according to whether symptoms occurred in the carotid or vertebrobasilar distribution and by the duration of symptoms. Transient ischemic attacks (TIAs) seldom last more than a few minutes and never more than 24 hours. In ischemic stroke, the neurologic deficit has been present more than 24 hours and may be progressive, stable, or resolving [6].

About 80% of all cerebrovascular events are ischemic in origin, and most are associated with atherosclerotic disease. The risk of an ischemic event increases with age and is correlated with both systolic and diastolic blood pressure, diabetes, and a history of ischemic heart disease or previous stroke. Ischemic strokes are divided broadly into five categories: large vessel athero-thrombosis, small vessel or lacunar infarction, cardiogenic embolism, other defined causes, and cryptogenic stroke. However, more unusual causes of strokes include vasculitis, drug induced stroke, dissection, or hyper-coagulable states. Hemorrhagic strokes, however, result from the rupture of a blood vessel either into the subarachnoid space or into the parenchymal tissue [6].

Whether a stroke is ischemic or hemorrhagic, appropriate therapy depends upon discernment of its cause, allowing caregivers to prevent progression of the stroke and prevent subsequent strokes. A patient's clinical history is essential to determining the correct diagnosis, for the stroke's time course, progression, and accompanying symptoms greatly inform the investigation. Medical and neurologic examinations provide further insight into a patient's condition and may provide clues to other systemic illnesses that may be contributing factors. Laboratory analyses and neuroimaging have revolutionized our ability to diagnose and treat stroke quickly and accurately, and are areas of intense continuing investigation [5].

For both *ischemic stroke* and *primary hemorrhagic stroke*, the prelude to proper therapy is precise diagnosis that includes not only the extent and location of the infarcted brain, but knowledge of the arterial pathology and the extent of the pared collateral circulation. This is essential to try to devise therapy to prevent further cerebral damage and recurrence of the stroke. In this chapter, cerebrovascular disease is divided into the main primary ischemic and hemorrhagic stroke pathophysiologic. Ischemic cerebrovascular disease is divided into two broad categories: thrombotic and embolic. Cerebral embolic stroke usually occurs abruptly but may present with stuttering, fluctuating symptoms [6].

ANATOMY OF THE CEREBROVASCULAR DISEASE

Anterior Circulation

The brain is supplied anteriorly by paired internal carotid arteries, which provide approximately 80% to 90% of the total cerebral blood flow. The left common carotid artery originates directly from the aortic arch, whereas the right common carotid artery originates from the innominate artery. The common carotid arteries bifurcate at the angle of the mandible into external and internal branches. The external carotid artery has many divisions, several of which supply the cerebral circulation through collaterals. The internal carotid artery can be divided into the cervical [or extracranial], intrapetrous, intracavernous, and supraclinoid segments. The cervical, intrapetrous, and intracavernous portions of the internal carotid artery have no branches. The supraclinoid segment gives rise to the ophthalmic and the posterior communicating arteries before bifurcating into its terminal branches, the anterior and middle cerebral arteries. The intracavernous and supraclinoid segments of the internal carotid artery are referred to as the carotid siphon [7].

Posterior Circulation

The vertebral arteries supply 10% to 20% of the total cerebral circulation. Both vertebral arteries originate from the first portion of their respective subclavian arteries and then enter the vertebral canal at the transverse foramina of the sixth cervical vertebra. The vertebral arteries unite to form the basilar artery, which then branches into the right and left posterior cerebral arteries. The posterior circulation supplies the brainstem, cranial nerves, cerebellum, and the occipital and temporal lobes of the cerebrum [7].

Circle of Willis

The anterior communicating artery connects the two anterior cerebral arteries. The posterior communicating artery connects the internal carotid arteries [anterior circulation] to the posterior cerebral arteries [posterior circulation]. This interconnecting network, which is termed the circle of Willis, is completely intact in 20% to 40% of individuals and allows for collateral flow between the hemispheres and the anterior and posterior circulations [Figure 1].

Figure 1.1. Configuration of the terminal branches of the vertebral and internal carotid arteries and their interconnections to form the circle of Willis.

PATHOPHYSIOLOGY OF CEREBROVASCULAR DISEASES

A disruption of arterial flow results in rapid dysfunction of the underlying brain tissue due to two processes: [1] loss of oxygen and glucose necessary for cell processes, and [2]

various alterations to cellular metabolism leading to loss of the cells integrity and cell death. Several changes occur acutely with ischemia: venous blood darkens with decreased oxygen saturation, blood becomes thicker [more viscous], the area of ischemic tissue pales, and arteries narrow. At a molecular level, the normal cellular processes are disrupted (e.g., Krebs cycle) with ATP depletion, increased intracellular calcium and extracellular potassium. Ischemic cells release the excitatory neurotransmitters glutamate and aspartate, leading to an influx of sodium and calcium leading to disruption of the cell membrane and cellular swelling [edema] with cell death [7].

The core region of infarcted tissue is surrounded by a penumbra which represents a zone of hypo-perfused tissue which is vulnerable but may remain viable. The extent of tissue injury is dependent upon the magnitude and duration of the drop in cerebral blood flow which is also dependent upon the support of collateral blood supply from other neighboring arteries. A reduction in cerebral blood flow is often first noted in the farthest territory supplied by that blood vessel. The region representing the boundary of blood flow from two neighboring vessels is termed the border zone, or watershed. Although the core region is irreversibly damaged, the ischemic penumbra has a temporary potential for salvage before progressing to infarction. The focus of current acute ischemic stroke therapy is to restore cerebral blood flow and salvage the penumbra, and stroke research continues to look for a way to extend the timeframe for this to occur by stabilizing the neurochemical milieu or reducing metabolic requirements [7].

Stroke occurs when there is disrupted blood flow to an area of the brain. The brain is perfused by anterior and posterior circulations. The anterior circulation begins with the carotid arteries and perfuses the anterior four fifths of the brain. The internal carotid arteries give off the ophthalmic branch before terminating at the circle of Willis, branching into the anterior and middle cerebral arteries. The posterior circulation supplies only one fifth of the brain and is derived from the vertebral arteries. The vertebral arteries first supply the cerebellum via the posterior inferior cerebellar arteries. The vertebral arteries then join to form the basilar artery. The basilar artery branches to form the posterior cerebral arteries that supply the occipital lobes. Arterial and cardiac abnormalities [8] (see Figure 1.2) often develop and lead to ischemic stroke. The most common cause of ischemic stroke is atherosclerosis of large and small arteries.

When atherosclerosis of an arterial wall leads to thrombus formation, there is partial or complete disruption of blood flow (thrombotic stroke). The thrombus may also dislodge and occlude a more distal artery [embolic stroke]. Large artery pathology commonly occurs in the aortic arch, carotids, and major cerebral vessels. Small vessel atherosclerosis may involve intracranial or penetrating arteries, with more focal or limited brain injury occurring (lacunar stroke). The most common cardiac abnormalities leading to stroke are atrial fibrillation, valvular disease [especially mitral stenosis], and poor ejection fraction. These cardiac problems predispose to thrombus formation, with dislodged thrombi [emboli] occluding cerebral vessels. Less common causes of ischemic stroke include drug use, arterial dissection, fibromuscular dysplasia, arteritis, hypercoagulable states, and migraines [8].

Hemorrhagic strokes comprise approximately 20% of total strokes and are divided into intracerebral and subarachnoid types. Intracerebral hemorrhage is usually caused by hypertensive vascular disease, with bleeding most often into the putamen, thalamus, pons, or cerebellum. Subarachnoid hemorrhage (SAH) is typically the result of leaking from a saccular aneurysm, but may be secondary to an arteriovenous malformation or other vascular

abnormality. A wide spectrum of pathology including atherosclerosis, aneurysmal disease, dysplasias, and arteriopathies can affect the cerebrovascular circulation. Atherosclerosis of the carotid bifurcation, however, is the most common lesion that produces symptoms. Atherosclerosis is the pathological process most often responsible for cerebrovascular insufficiency. The carotid bifurcation is the predominant location for atherosclerotic disease [9].

Figure 1.2. The most frequent sites of arterial and cardiac abnormalities causing ischemic stroke. [From Albers EW, et al.]

Low shear stress in well-defined regions of the carotid bulb appears to stimulate the formation of atherosclerotic plaque. Symptoms of cerebrovascular disease may be the consequence of distal embolization from an atherosclerotic plaque or hypoperfusion related to a flow-limiting lesion. The most common cause of a cerebral ischemic event, however, is embolization. Platelets accumulate on the thrombogenic surface of an irregular or ulcerated plaque. Symptoms are produced when these platelet and cholesterol aggregates embolize and obstruct the more distal circulation. Plaque hemorrhage with rupture and extrusion of thrombus into the arterial lumen is another mechanism by which embolization can occur. Although an ulcerated atherosclerotic lesion can embolize even if there is no luminal

encroachment, highly stenotic plaques are more often ulcerated and thus more likely to produce emboli [10].

Hypoperfusion related to carotid artery stenosis is a less common source of symptoms because extensive collateral circulation is provided by the contralateral carotid and vertebral arteries via the circle of Willis and by the external carotid artery via transcranial connections. The fact that 90% to 95% of patients undergoing CEA do not develop cerebral insufficiency during clamping of the carotid artery confirms that, in the majority of individuals with progressive atherosclerotic disease, this collateral network is adequate to prevent cerebral ischemia [11].

Atherosclerosis commonly involves the large extracranial vessels that arise from the aortic arch. Although the carotid bifurcations are most frequently involved, atherosclerosis can also occur at the origins of the common carotid or vertebral arteries or in the intracranial vessels, including the carotid siphon and the basilar artery. Atherosclerosis probably results in ischemic symptoms through several mechanisms. The most widely accepted is platelet activation and aggregation at the site of an ulcerated complex atherosclerotic plaque, with production of thromboxane A_2 from arachnidonic acid resulting in further platelet aggregation. Aggregated platelets can embolize, with specific symptoms dependent on the vessel of embolization. The severity of symptoms depends on the duration of vessel occlusion and the degree of collateral flow through tiny leptomeningeal and other end artery anastomoses [5]. Atherosclerosis may also result in vessel stenosis or occlusion. In this situation, symptoms depend largely on how rapidly stenosis develops and the extent of collateral flow available through the circle of Willis and from extracranial–intracranial anastomoses. The availability of collaterals varies considerably among different people; thus, the same degree of stenosis or occlusion can result in very different symptoms. For example, total occlusion of the internal carotid artery may be asymptomatic in one individual, but result in a disastrous stroke in a patient with congenital absence of portions of the circle of Willis. Other factors that are probably important in determining outcome are blood viscosity, blood glucose, blood oxygen carrying ability, and tissue metabolic demand [13-14].

Stenosis of small intracranial arteries can also result in ischemic symptoms. Patients with hypertension or diabetes can develop atherosclerosis of small intracranial arteries. A more common occurrence is the development of hypertension-related lipohyalinosis and fibrinoid necrosis in small end arteries and arterioles. When this results in occlusion, there is no available collateral flow, and a tiny "lacunar stroke" results. Among the many lacunar syndromes are pure motor hemiparesis with or without dysarthria [due to lesions of the internal capsule or pons] and pure sensory stroke [due to lesions in the thalamus]. Patients with lacunar strokes almost never have field defects, aphasia, or other higher cortical function loss [15].

Emboli from the heart cause 10 to 20% of ischemic strokes. Although many cardiac conditions predispose to cerebral embolization, the two most common are atrial fibrillation and acute myocardial infarction. The risk of stroke is increased five times in patients with atrial fibrillation and fifteen times if there is associated mitral stenosis. Strokes complicate acute myocardial infarctions approximately 2% of the time. The risk is highest in patients with large infarctions, those with congestive heart failure, or those with anterior infarctions where there is hypokinesis of the left ventricular apex. Emboli usually lodge in end arteries that have poor collateral circulation and therefore often cause major neurologic deficits. The middle cerebral artery distribution is usually affected [5-6].

CARDIAC CONDITIONS ASSOCIATED WITH EMBOLIZATION

Other rare causes of ischemic stroke include hematologic disorders [polycythemia, thrombocytosis, dysproteinemias, sickle cell disease], fibromuscular dysplasia, carotid dissections, and intracranial vasculitis of several etiologies [lupus erythematosus, giant cell arteritis, syphilitic arteritis, granulomatous angiitis]. Clinical clues and past history will usually help identify these unusual conditions [5].

The development of saccular aneurysms of the circle of Willis is thought to occur gradually at bifurcation sites where the arterial media may be congenitally absent. The internal elastic lamina at these locations becomes fragmented, possibly accelerated by atherosclerosis. Aneurysms have a predilection for certain locations, especially the posterior communicating artery, anterior communicating artery, and middle cerebral artery. They are multiple in 20% of cases. Progressive enlargement seldom causes symptoms unless the aneurysm compresses an adjacent structure, for example the oculomotor nerve by a posterior communicating artery aneurysm [16-18]. Because cerebrovascular disorders are a diverse group of illnesses that are managed in very different ways, an accurate diagnosis is critical. The following points are important for proper diagnosis and management [19]: [See Table 1.1]

Table 1.1. Important points regarding diagnosis and management of strokes

S. No	Important points for diagnosis and management of strokes
1	Establish that a cerebrovascular event actually occurred, and determine the location of the event.
2	Decide if the event was ischemic or hemorrhagic.
3	Determine what steps are necessary for medical stabilization of the patient.
4	Determine the underlying pathophysiology that caused the event (e.g., atherosclerosis, embolus, aneurysm).
5	Determine what can be done to prevent future, possibly more devastating, events.
6	Decide if the occurrence of the cerebrovascular event may indicate an underlying disease (especially cardiac diseases).
7	When a fixed deficit already exists, establish the patient's potential for rehabilitation.

Differentiating between ischemic stroke and intracranial hemorrhage is usually easy because the latter is often much more catastrophic with precipitous onset of severe headache, nausea and vomiting, and clouding of consciousness. Hemorrhages of all etiologies tend to occur in younger patients than those afflicted by ischemic stroke. Although it is often said that

ischemic strokes occur at rest or during sleep, whereas hemorrhages occur during straining or exertion, this is not always a reliable rule. Although headaches are more common in hemorrhage, they can also occur in ischemic stroke, and not every patient with a hemorrhage has a headache. Vomiting within 15 minutes of onset is highly suggestive of hemorrhage. Small intracerebral hematomas may be indistinguishable from ischemic stroke. The differentiation is readily made by CT scan, which has become almost routine in evaluation of patients with stroke and is mandatory if anticoagulation is contemplated [20]. With long-term neurologic deficits due to cerebrovascular disease, it is important to assess the patient's ability for functional living. The quality of life of many patients is improved considerably by participation in a comprehensive rehabilitation program.

SUB-TYPES OF STROKE AND THEIR CATEGORIZATION

The two main categories of cerebrovascular disease are ischemic and hemorrhagic. Ischemic stroke is due to a lack of blood flow to part of the brain. Occlusion of a cerebral artery by a blood clot that travels from the heart or another vessel (embolus) or that develops within a cerebral artery [thrombus] results in an arterial ischemic stroke. Diminished cerebral blood flow due to narrowing of a blood vessel or decreased blood pressure also may result in ischemic brain injury. Less commonly, a blood clot develops within one or more veins that drain the brain, known as cerebral venous sinus thrombosis, and leads to venous infarction. Hemorrhagic stroke occurs when a blood vessel ruptures, leading to brain injury

As per pathophysiology strokes can be divided into three main categories like Ischemic, hemorrhagic and cerebral venous thrombosis (see Table 1.2 and Figure 1.3). The major categorization of stroke is whether it is *Ischemic* or *Hemorrhagic*. The archaic term “cerebrovascular accident” should not be used. *Ischemic stroke* (IS) or *cerebral infarction* occurs when an arterial flow to the brain is obstructed and accounts for ~85% of all strokes. *Hemorrhagic stroke* occurs when an artery or vein ruptures causing intracranial bleeding and accounts for ~15% of all strokes.

Hemorrhagic stroke occurs due to a blood vessel rupture in the brain. Its harmful effects are a resultant of: [a] hypoxia due to disrupted vascular supply; [b] irritant effect of releasing blood on brain parenchyma and vasculature; and [c] raised ICP due to continued bleeding, which may further restrict cerebral blood flow. In this respect, hemorrhagic strokes are more dangerous than ischemic strokes. There are two types of hemorrhagic stroke: intra-cerebral hemorrhage [generally occurs in small arteries or arterioles and is commonly due to hypertension, trauma, bleeding disorders, amyloid angiopathy, illicit drug use like amphetamines or cocaine, and vascular malformations], and sub-arachnoid hemorrhage [due to rupture of aneurysms from the base of the brain and bleeding from vascular malformations near the pial surface]. It constitutes only 10–15% of all strokes [21].

Table 1.2. Sub-tyapes of stoke and their causes

Ischemic Stroke or Infraction	Hemorrhagic strokes	Cerebral venous thrombosis
A. Large artery atherosclerosis	A. Intracerebral hemorrhage 1. Hypertension 2. Amyloid angiopathy 3. Arteriovenous Malformation (AVM) 4. Hematologic disorder 5. Hemorrhagic transformation of recent cerebral infarct 6. Hemorrhage into tumor	A. Dural sinus thrombosis
B. Lacunar or small vessel arteriosclerosis		
C. Cardioembolism		
D. Cryptogenic	B. Subarachnoid hemorrhage 1. Saccular aneurysm 2. Arteriovenous malformation 3. Hematologic disorder 4. Mycotic (infectious) aneurysm	B. Cortical venous thrombosis
E. Other known cause 1. Cervicocephalic dissection 2. Coagulopathy 3. Non-atherosclerotic arteriopathy (e.g., CADASIL) 4. Metabolic disorders (e.g., MELAS) 5. Migraine 6. Vasculitis 7. Drug abuse		

Figure 1.3. Schematic showing different types of stroke and cascade of events following ischemia.

ATHEROSCLEROSIS AND STROKE

Atherogenesis is a decade-long process which involves luminal obstruction by cellular and extracellular substances. The pathogenetic process from onset of atherosclerotic changes in cerebrovascular or extracranial circulation to precipitation of acute ischemic stroke with its consequent cell damage is complex and many of the intermediary steps are not fully understood. Changes may manifest in the form of: [a] *fatty streak*, earliest lesions seen as yellowish areas of discoloration of intima, due to accumulation of lipid-filled macrophages [foam cells] in approximately 30% children below 5 years [22]; [b] *more advanced lesions with massive extracellular lipid* at the branching points of arterial vessels, in late childhood and early adolescence [23]; [c] *complicated fibrous plaques*: central acellular area of lipid covered by a cap of smooth muscle cells and collagen, seen in the third decade of life [23]. Persons with risk factors for atherosclerotic disease (e.g., hypertension, hypercholesterolemia, cigarette smoking) tend to have clinically advanced atherosclerotic lesions with increased frequency. Sequence of events in atherogenesis is:

1. Injury to Arterial Wall

In his “response-to-injury” theory, Ross had hypothesized that, atherosclerosis is the effect of the complex interplay among monocytes, lipoproteins, platelets, lymphocytes, and smooth muscle cells in the intimal layer [24]. Three-tier pathophysiologic classification system of injury to arterial wall was put forth by Ip et al. in 1990 [23].

- *Type I injury*: Chronic minimal injury with functional alterations of endothelial cells without significant morphological changes, primarily caused by the turbulence of blood flow. Other contributory factors being hypertension, hypercholesterolemia, circulating vasoactive amines, immunocomplexes, viral infections, and tobacco smoke.
- *Type II injury*: Endothelial denuding and superficial internal injury, possibly due to toxic products released by accumulating macrophages in the intima. These changes may be accompanied by platelet deposition with or without thrombus formation, and subsequent thrombus incorporation.
- *Type III injury*: Manifested by deep intimal and medial damage, accompanied by marked platelet aggregation and mural thrombosis, generally following plaque rupture.

2. Role of Monocytes and T-Lymphocytes in Foam Cell Transformation

The next important events are:

- *Circulating monocyte adhesion*: Abnormal shear stress at atherosclerotic lesion-prone sites in the circulatory system enhances the production of certain transcription factors, which promotes the expression of endothelial vascular cell adhesion

molecule [VCAM], which is imperative for monocyte binding to endothelial cells [25].

- *Monocytes insinuation* between the tight junctions of the endothelial cells to enter the subendothelial space.
- *Activation of immune mechanism*: In the form of T-lymphocyte activation, in both early fatty lesions and in advanced fibrous lesions, which helps monocytes migration and its transformation into “foam cell”.

3. Oxidation of LDL-Cholesterol

Oxidation of LDL cholesterol induced by free radicals produced by macrophages, endothelial cells, or smooth muscle cells, participates by:

- a) Formation of foam cells;
- b) Cytotoxic properties promoting endothelial injury;
- c) Chemoattractant for circulating monocytes; and
- d) Inhibiting egress of macrophages from plaques [26].

4. Smooth Muscle Cell Migration and Proliferation

A number of molecular factors may play a role in this vital plaque-forming process. They include growth factors [e.g., platelet-derived growth factor, or PDGF, a polypeptide released from blood platelets and endothelial cells that may attract smooth muscle cells to the intima and encourage them to divide]; eicosanoids [which can stimulate the hydrolysis of cholesterol ester, producing free cholesterol]; certain cytokines [e.g., tumor necrosis factor, interleukin-1 and interferon]; and nitric oxide which acts to dilate blood vessels.

5. Role of Platelet

Platelet aggregation and adhesion promoted by toxic products released by macrophages and by moderate damage to the internal surface with denudation of the epithelium have vital roles in the progression of atherosclerosis [23].

6. Plaque Fissuring and Thrombus Formation

The process of plaque destabilization [fissuring and rupture, followed by thrombus formation] is not fully understood.

- **Plaque fissuring is possibly due to:**
 - a) Loss of an internal lattice of collagen supporting the cap of the plaque., making it vulnerable to circumferential stress during systole;

- b) Infiltration of the cap tissue with foam cells, which possibly weakens the tissue by passively distorting the spatial arrangement of the connective tissue matrix or by actively destroying connective tissue matrix protein by lytic mechanisms [27].
- **Thrombus formation occurs by:**
 - **Platelet activation:** On coming in contact with the sub-endothelial collagen, exposed by way of plaque rupture, circulating platelets get activated, and subsequently aggregate and adhere, through interaction with platelet surface receptors [most important being GP-Ib-IX] and sub-endothelial protein ligand von Willebrand factor [VWF]. An association between elevated vWF concentrations and arterial thrombosis has been described [28].
 - **Platelet activation and blood flow:** Under high fluid shear-stress conditions, as in atherosclerosis, there is evidence that platelet aggregation depends on the binding of VWF to platelet GPIIb/IIIa, blockade, of which inhibits platelet aggregation and thrombus formation without disturbing the initial platelet adhesion [29 Stoll G 2008].
 - **Activation of the coagulation cascade:** Endothelial injury constitutes the primary impetus for the initiation of the extrinsic pathway of the coagulation cascade. Activated platelets, apart from forming the backdrop of the clotting process, also acquire enhanced capacity to catalyze interactions between activated coagulation factors [which normally circulate as inactive precursors: *zymogens*]. Factor Xa, is the active catalytic component of the “prothrombinase” complex, which converts prothrombin to thrombin. Thrombin cleaves fibrinopeptides [FPA, FPB] from fibrinogen, allowing the resultant fibrin monomers to polymerize, and converts Factor XIII to XIIIa, which crosslinks [XL] the fibrin clot. Thrombin accelerates the process by its potential to activate Factors V and VIII, while a number of natural plasma inhibitors retard clotting, including C1-inhibitor [C1 INH], tissue factor pathway inhibitor [TFPI], and antithrombin II [ATIII]. The fibrin molecules aggregate together, trapping platelets, erythrocytes, and leukocytes to form the thrombus. Subsequently, there is a tendency for the clot to enlarge as blood flow slows around it, resulting in enlargement of size [*“propagating thrombus”*].
 - **Physiologic-subtypes of thrombosis related ischemic stroke:**
Ischemic stroke with different etiologies, possibly have a link based on the process of thrombosis:
 - Atherothrombotic occlusion of larger arteries [e.g., carotid, middle cerebral, basilar]: Most common causes of primary large vessel occlusive cerebrovascular disease, and also is the most common cause of stroke.
 - Embolism is the second most common cause of stroke. Most are due to cerebral arterial atherothrombosis; or may also arise from other cardiogenic sources and deep vein thrombosis.
 - Microatheroma of an influx of fat-like materials [lipohyalinosis] affects small vessels; and most prominently causing lacunar strokes.

7. The Potential Outcomes of Plaque Fissuring

It includes

- a) Sealing of the fissure with fibrosis of incorporating thrombus; or
- b) Mural intra-intimal and intra-luminal thrombosis, resulting in partial or transient reduction in blood flow [precipitating transient ischemic attacks: TIA]. It may progress to occlusive thrombosis, which, if persistent due to absence of collateral flow, can lead to ischemic stroke [23 IP JH 1990].

8. Evolution of Cerebral Atherothrombosis

Thrombosis may evolve over a few minutes, or take hours or even days. A stroke that is actively progressing as a direct result of increasing occlusion and ischemia is termed '*stroke in evolution*' or '*progressing stroke*'. A large blood vessel may evolve over a longer period of time, as compared to a smaller vessel, and there may be warning signs like TIA. Damage in ischemic stroke may result not only from infection, but also from edema, which generally peaks in 2–5 days. [I] *Hemorrhagic conversion*: Natural consequence of reperfusion of blood through damaged blood–brain barrier, in ischemic stroke, generally has 'bland' infarction associated with secondary bleeding. This is referred to as hemorrhagic conversion or hemorrhagic transformation [HT], and is characterized by gross parenchymal hematoma with possible intraventricular extension, midline shift and herniation; along with widespread leukocyte infiltration and macrophage invasion [30]. HT may be seen as hemorrhagic infarction [HI] or, less commonly, parenchymatous infarction [PH]. Though both have different incidences, pathogenesis, and clinical outcome, but distinguishing HI and PH on CT may be difficult. On CT, HI appears as a discontinuous heterogeneous mixture of high and low densities occurring within the vascular territory of the infarct. In contrast, PH appears as a discrete, homogeneous collection of blood that often exerts mass effect and may extend beyond the original infarct boundaries or even into the ventricles [30].

Recent studies have suggested the role of an abnormal expression of some matrix metalloproteinases [MMPs] which can degrade almost all components of the extracellular matrix and basal lamina such as laminins, fibronectin, or type IV collagen, weakening brain microvessels and predisposing them to rupture and increasing the risk of cerebral hemorrhage and precipitate hemorrhagic transformation events after stroke [31]. Previous animal models [32–33] have demonstrated an abnormal expression of MMP-2 [Galatians A] or MMP-9 [Galatians B] after cerebral ischemia and in lipopolysaccharide-injured brains [34], contributing to brain injury and BBB breakdown. Further, Asahi et al. 2001 and Sumii et al. 2002 [35–36] reported that pharmacological or genetic inhibition of MMP-9 has caused a significant reduction in size of the infarct, as well as the risk of hemorrhagic complications, while Wang et al. 2003 [37] and Tsuji et al. 2005 noted tissue plasminogen activator-associated hemorrhage and edema appeared to be correlated to MMP-9 dysregulation. Investigations dealing with ischemic stroke in human subset have revealed high MMP-9 levels in peripheral blood, with MMP-9 levels showing correlation with poor neurological outcome, infarct growth, and hemorrhagic transformation events [38–39].

Rossel et al. 2008 [40] have reported a strong neutrophil infiltration in the infarcted and hemorrhagic areas with local high MMP-9 content closely related to basal lamina collagen IV degradation and blood–brain barrier breakdown. Hemorrhagic infarction [HI] occurs regularly in the natural evolution of acute embolic stroke and is usually asymptomatic. Autopsy studies of HI may vary from patchy petechial bleeding to more confluent hemorrhages, with an occurrence rate ranging from 51% to 71% of recent embolic strokes [30]. According to another estimate [41], approximately 20% of patients with cardioembolic stroke have hemorrhagic transformation in the infarcted zone, usually occurring within 48 h, and is rare in the first 6 h. HI has been often explained as a result of reperfusion of the vascular bed of the infarct, such as would occur after fragmentation and distal migration of an embolus or after early reopening of a large vessel occlusion in the setting of a large infarction; the full pressure of arterial blood into hypoxic capillaries results in a diapedesis of red cells through their hypoxic walls [42]. It has been observed that HI may develop in areas distal to a persisting occlusion, suggesting that reperfusion is not always a prerequisite for this phenomenon. Many studies have found strong correlation with risk factors like:

- 1) One or more surges of arterial hypertension;**
- 2) Associated hyperglycemia; and**
- 3) Restoration of blood flow to ischemic territories.**

Possible mechanism for this is marked tissue energy depletion accompanied by acidosis damaging brain vessels, causing leakage of edema fluid and red blood cells.

Parenchymatous infarctions (PH) occur less frequently, but are often symptomatic due to extension and mass effect beyond the original infarct territory [30]. In contrast to HI, it has been proposed that the pathogenesis of PH may involve “ischemic necrosis resulting in the rupture of small penetrating vessels analogous to hypertensive hemorrhage, leading to massive bleeding”. Trials of thrombolytic therapy for acute ischemic stroke, has revived interest in this, since PH appears to be associated with anticoagulation therapy [26, 43].

Treatment approaches for ischemic stroke and cerebrovascular diseases have largely focused on reperfusion of the ischemic brain tissue—for example with the thrombolytic agent recombinant tissue plasminogen activator [rt-PA, The National Institute of Neurological Disorders and Stroke rt-PA Stroke Study Group, 1995]—and on neuronal protection, mainly from damage caused by excitotoxic amino acids such as glutamate. Over the past 15 years it has been increasingly appreciated that inflammation alone, or in combination with systemic immune system responses, may be an important contributing factor in stroke-related brain injury and stroke outcome, as well as in the development of atherosclerotic cerebrovascular disease. Elements of the inflammatory process may provide promising targets for the treatment of acute ischemic stroke and for vascular disease prevention.

The role of inflammation in atherosclerotic cerebrovascular disease has also been increasingly recognized to the effect that atherosclerosis is no longer regarded as a disorder of lipid storage within blood vessels but now, primarily, as a disorder of chronic inflammation [44]. These changing concepts of the role of the immune system and inflammation in stroke and cerebrovascular disease have led to searches for new treatment and prevention strategies. Here we discuss the current state of knowledge about inflammation and the immune system in stroke and atherosclerosis and discuss potential therapeutic strategies.

ATHEROSCLEROTIC CEREBROVASCULAR DISEASE AND INFLAMMATION

The study of cerebrovascular disease has advanced markedly in recent years with advances in non-invasive imaging methods such as MR angiography and CT angiography as well as an improved understanding of the immune system in the pathogenesis of atherosclerosis. Atherosclerotic cerebrovascular disease is a common cause of strokes and shows a predilection for sites such as the bifurcation of the common carotid artery into the internal and external carotid arteries and the aortic arch and the major intracranial arteries such as the basilar artery and the middle cerebral arteries. Occlusive atherosclerotic vascular disease of these large extracranial arteries is responsible for as many as 20–30% of ischemic strokes and intracranial steno-occlusive disease causes around 5–10% of ischemic strokes.

Atherosclerosis is characterized by the formation of plaques within the innermost layer of artery walls. It has traditionally been regarded as a disorder of lipid storage but is now regarded as a chronic inflammatory disorder. The plaque commences with the deposition of cholesterol-containing lipoproteins in the vessel wall. The first inflammatory cells involved are believed to be circulating monocytes [rather than neutrophil polymorphs]. These migrate across the endothelial lining from the blood or from the lymphatics and develop into tissue macrophages or into dendritic cells. The macrophages [“foam cells”] accumulate cholesterol in the artery wall. The resulting fatty streaks commence as early as the late teen years or the early 20s and may regress or progress throughout life. Lesions are typically asymptomatic, at least initially. Many fatty streaks develop into atheromatous plaques that contain extracellular debris and cholesterol. A fibrous cap is formed over the lipid-containing plaque by smooth muscle cells from the arterial wall and possibly from blood-derived progenitor cells. The collagen stabilizes the lesion and prevents debris, lipids and pro-coagulant material from reaching the bloodstream [45].

Pro-inflammatory lymphocytes [i.e., CD4⁺ Th1 cells] also contribute to and may accelerate atherosclerotic plaque formation [44]. CD4⁺ CD28[–] cells [mentioned previously] are a rare subset of CD4⁺ T cells that are long-lived, secrete high levels of γ -IFN and are directly cytotoxic. These cells preferentially infiltrate unstable plaques and contribute to increased endothelial cell lysis in patients with acute coronary syndromes [46]. Naturally arising regulatory T cells [CD4⁺ CD25⁺] have recently been shown to be potent inhibitors of the development of atherosclerosis in several mice models and may be a promising target for vascular disease prevention [47]. It has also been suggested that common infections may be associated in the pathogenesis of atherosclerosis. Specific organisms that have been studied include *Chlamydia pneumoniae*, herpes viruses, *human immunodeficiency virus*, *Helicobacter pylori*, and organisms associated with periodontal infections; however definitive proof of causal associations are lacking.

The atheromatous plaque grows silently for years or even decades without producing clinical symptoms. However, trace amounts of pro-inflammatory cytokines released from cells within the plaque, including IL-6, reach the bloodstream and stimulate C-reactive protein [CRP] secretion by the liver. CRP can be detected in the peripheral blood and is an independent marker of risk for myocardial infarction and probably for stroke in healthy individuals. Atherosclerotic plaques precipitate ischemic strokes by rupturing, leading to superimposed thrombus formation and embolism. They may also lead to strokes if the

narrowing becomes particularly severe, >50%. The risk of stroke is greater with the greater degrees of narrowing as there is also associated hemodynamic insufficiency. Conventional angiographic techniques and non-invasive modalities [ultrasound, MRA, CTA] are used to detect occlusive arterial disease, and in the case of stroke prevention a narrowing of $\geq 50\%$ of the internal carotid artery is used in decision-making for referral of patients for carotid endarterectomy.

Certain plaques are particularly prone to rupture. These “vulnerable plaques” contain abundant inflammatory cells and have thin collagen caps. The atheroma’s vulnerability to rupture is correlated with higher cellular infiltrates of macrophages and activated T cells. In symptomatic carotid artery plaques elevated ICAM-1 expression [relative to asymptomatic plaques] has been found and the ICAM-1 expression was greatest in the high-grade region of the plaque. Vulnerable plaques are also not necessarily the largest plaques, particularly in patients with coronary artery disease, and current angiographic methods are of limited value in their recognition. However, new MRI methods using novel contrast agents are now being used to better study the features of vulnerable plaques.

RISK FACTORS FOR STROKE

As mentioned above, atherosclerotic vascular disease is a common cause of ischemic stroke and also predisposes patients to coronary artery disease, itself a risk factor for stroke. Vascular disease also increases with age and is increased in patients with hypertension, diabetes, a smoking history and hyperlipidemia. Hypertension is the major risk factor for hemorrhagic stroke. The “metabolic syndrome” is a cluster of risk factors [truncal obesity, hyperglycemia, hypertriglyceridemia, hypertension and low HDL-cholesterol] associated with increased cardiovascular disease risk. Some immune and inflammatory risk factors may include recent infection that increases the risk of stroke to a modest degree and the possible mechanisms for this are being investigated. Periodontal disease, another factor shown to be independently associated with stroke and coronary artery disease, is believed to be associated with chronic inflammation and endothelial dysfunction [48]. Lipoprotein associated phospholipase A2 (a pro-inflammatory enzyme associated with low density lipoprotein) is approved by the Food and Drug Administration as a risk marker for stroke and coronary artery disease. Other inflammatory markers in the blood are showing promise as independent risk factors; these include elevated plasma levels of high sensitivity-CRP, IL-6 and the total white blood cell count [49].

MIXED CEREBROVASCULAR DISEASE

The concept of “mixed cerebrovascular disease” has been proposed as a framework for better understanding stroke, and for improving stroke prevention efforts [50]. Mixed cerebrovascular disease incorporates clinical and subclinical stroke with hemorrhagic and ischemic stroke. The clinical stroke syndromes thus incorporate the typical variety of presentations encountered, with intracerebral hemorrhage and ischemic stroke subsets (small

vessel disease, large vessel disease, cardiogenic, other). Subclinical stroke syndromes include silent ischemic stroke and cerebral microbleeds.

Cerebral white matter disease (of aging) is an additional component of mixed cerebrovascular disease. There are both strengths and weaknesses of this conceptual approach. A principal benefit of characterizing a given patient as having “mixed cerebrovascular disease” is that the clinician is immediately confronted with the fact that, going forward with stroke prevention efforts, this patient will require a complex strategy. Simply relying on “antiplatelet medications” for prevention of cerebral infarction will be insufficient. The principal weakness of this approach is that it may simply be too inclusive. For example, cerebral white matter changes are ubiquitous in the population of age 65 and older, with more than 95% of individuals showing at least some white matter change on magnetic resonance imaging (MRI) [51]. Only about one-third of these changes are probably sufficient to be characterized as “disease”, but the gradation between normal and pathological change remains unclear.

A similar problem may arise with the inclusion of cerebral microbleeds. Microbleeds are present in approximately 20% of the population beginning at age 60, a proportion that increases to nearly 40% by age 80 [52]. Pathological studies reveal a much higher prevalence over the age of 70 [53-54], but it is unclear whether both MRI and neuropathological findings are demonstrating the same entity. However, this difficulty may be surmounted by simply focusing on the inclusion of MRI-demonstrable cerebral microbleeds, using gradient echo or the more sensitive susceptibilityweighted imaging sequences.

To summarize, the use of mixed cerebrovascular disease as a conceptual and clinical framework appears feasible. Inclusion of cerebral white matter disease may be problematic. Nevertheless, a characterization of stroke syndromes that incorporates clinical and subclinical ischemic and hemorrhagic disease may help quickly characterize the complexity of many stroke patients.

Mixed cerebrovascular disease represents the Scylla and Charybdis of modern stroke neurology. The stroke neurologist must navigate between the apparent extremes of ischemic and hemorrhagic processes. For the most part, the patient will come to the attention of the neurologist with symptoms suggesting ischemic stroke, and cerebral microbleeds and white matter disease will be identified incidentally. Given its relationship to hemorrhagic stroke, the presence of cerebral microbleeds is particularly challenging. An attractive therapeutic strategy for mixed cerebrovascular disease is one that targets both the coagulation system and the vessel wall. Platelet agents may be focused on receptor antagonism, but inhibition of signal transduction pathways is an important alternative strategy for inhibition of platelet activation pathways. Inhibition of platelet signal transduction can be achieved by manipulation of platelet second messenger pathways and/or amplification of effects of endothelial-derived molecules [e.g., prostacyclin and nitric oxide] that activate cyclases producing elevated levels of intracellular cyclic adenosine monophosphate [cAMP] and cyclic guanosine monophosphate (cGMP) [55]. Importantly, cAMP pathways have well-described major roles in development of the blood–brain barrier [56]. Platelet levels of cyclic nucleotides have critical regulatory function, so that elevated levels of cAMP and cGMP interfere with all known platelet activation pathways [55].

Signaling of cyclic nucleotides is modulated by their hydrolysis by phosphodiesterases (PDEs), with the latter regulated by any of the more than 60 isoforms of the eleven families of PDE inhibitors [55]. Notably, the PDE inhibitors dipyridamole and cilostazol have been

shown to have beneficial actions for ischemic stroke prevention [57-60]. However, neither drug has been considered a first-line agent for stroke prevention efforts. Dipyridamole, a relatively nonspecific PDE inhibitor with effects on both PDE3 and PDE5 [55], has been shown beneficial for the prevention of ischemic stroke, with stroke risk reduction comparable to that seen with aspirin [57]. Dipyridamole is known to have dual actions, combining platelet anti-aggregant effects and vessel wall protection [61]. Platelet actions are generated by adenosine-mediated effects, along with potentiation of the platelet anti-aggregatory effects of prostacyclin and nitric oxide [61]. Dipyridamole inhibits red blood cell uptake of adenosine, resulting in elevated plasma adenosine leading to stimulation of platelet adenylyl cyclase and increased platelet cAMP [57, 61]. Vessel wall protection effects of dipyridamole are produced via anti-oxidative effects and by inhibition of platelet-monocyte interactions [61].

Recent work with animals has emphasized the potential for dipyridamole in stroke prevention as well as treatment. In summary, an attractive therapeutic strategy for mixed cerebrovascular disease is one that utilizes agents acting on both platelets and vessel wall. Several PDE inhibitors have those dual actions. Dipyridamole and cilostazol have already been shown effective in ischemic stroke prevention clinical trials and may be particularly useful for patients with mixed cerebrovascular disease.

Mixed cerebrovascular disease consists of ischemic and hemorrhagic phenomena, both clinically evident diseases as well as subclinical processes. Ischemic stroke, subclinical infarct, and white matter disease of aging (or leukoaraiosis) combined with intracerebral hemorrhage and cerebral microbleeds constitute this entity. The incorporation of these processes into a single entity creates a novel concept in stroke diagnostics. The treatment of mixed cerebrovascular disease presents the stroke clinician with a profound dilemma. What is the way out of this conundrum? Use of PDE inhibitors, combining platelet and vessel wall effects, provides one possible strategy. There are, no doubt, other approaches that will become increasingly obvious in the coming decades.

In adults, arterial ischemic stroke is commonly associated with advancing age, hypertension, atrial fibrillation, smoking, and diabetes mellitus [62]. Other risk factors include obesity, cardiac disease, carotid stenosis, sickle cell anemia, recent infection, and alcohol abuse. In young adults abnormalities of blood vessel structure such as arterial dissection, non-inflammatory vasculopathies, and vasculitis are also associated with stroke [63]. In addition, hematologic abnormalities leading to hypercoagulability may play a role in selected cases [64]. Cerebral venous sinus thrombosis, which can result in either ischemic or hemorrhagic infarction, is associated with oral contraceptive use; infections of the head, neck, or central nervous system; malignancy; prothrombotic states; inflammation; and pregnancy [65]. In fact, the risk of both ischemic and hemorrhagic stroke is increased during pregnancy and the post-partum period [66].

A common risk factor for primary intracerebral hemorrhage in adults is hypertension. Other risk factors include amyloid angiopathy, elevated cholesterol, treatment with anticoagulants, heavy alcohol use, smoking, renal dialysis, and use of sympathomimetic drugs such as cocaine and amphetamines [62]. Vascular malformations such as aneurysms and arteriovenous malformations [AVMs] are much less common causes of hemorrhagic stroke in adults [67-68]. Risk factors for cerebrovascular disorders in children are quite different from adults. Congenital or acquired heart disease; congenital or acquired abnormalities of arterial structure such as arterial dissection, transient cerebral arteriopathy of childhood, moyamoya disease, and vasculitis; prothrombotic states; sickle cell anemia; and infection are common

risk factors for arterial ischemic stroke in children [69-71]. In neonates, maternal and fetal physiologic factors associated with pregnancy likely contribute to the risk of arterial ischemic stroke, as do congenital heart disease, prothrombotic states, maternal infection, and placental abnormalities [72]. Pediatric cerebral venous sinus thrombosis has been associated with dehydration, prothrombotic states, head and neck infection, trauma, surgery, malignancy, and inflammatory conditions [73]. Hemorrhagic stroke in children is commonly associated with vascular malformations such as AVMs, aneurysms, and cavernous malformations, although hematologic abnormalities and other medical conditions can be precipitants [74]. In contrast, the cause of hemorrhagic stroke in term neonates is often unknown [75].

TREATMENT OF CEREBROVASCULAR DISORDERS

The acute treatment of stroke depends on the mechanism of injury. In adults with arterial ischemic stroke, intravenous infusion of tissue plasminogen activator [tPA], a drug that lyses blood clots, is the only FDA approved treatment. Widespread use of this drug is limited by the need to administer it within 4.5 h of stroke symptom onset [76], and as a result fewer than 5% of adults with acute stroke receive this treatment [77]. Other acute stroke treatments include aspirin, intra-arterial administration of tPA [78], mechanical clot disruption, and endovascular removal of thrombus with a clot-retrieval device [79]. Surgical decompression can be beneficial in patients with space-occupying infarction [80]. Ongoing studies are evaluating the role of therapeutic hypothermia in the management of acute stroke [81].

To prevent future strokes, treatment with an antiplatelet or anticoagulant medication is recommended [78 Albers GW et al. 2008], in addition to treatment of stroke risk factors such as hypertension, elevated cholesterol, and diabetes. Stent placement may also be useful for secondary prevention in selected cases of arterial stenosis [79]. None of these treatments have been studied in children, although the use of antiplatelet or anticoagulant medications for secondary prevention is recommended in most cases [82]. Chronic transfusion therapy has been shown to prevent stroke in children with sickle cell anemia [83], and revascularization surgery for moyamoya disease also prevents stroke recurrence [84]. Anticoagulation is the treatment of choice for acute cerebral venous sinus thrombosis in adults and children [78].

Following intracerebral hemorrhage, acute treatment may include surgical evacuation of hemorrhage, placement of a temporary ventriculostomy catheter if obstructive hydrocephalus develops, and intraventricular infusion of thrombolytic medications to augment clearance of blood from the ventricles. Infusion of activated recombinant factor VII [a coagulant] has been shown to decrease the amount of hemorrhage expansion and garnered much recent enthusiasm, but this treatment has not consistently been associated with improved outcome [85]. Certain patient populations may benefit from this treatment, but identification of these groups will require further study. Preventative treatment of recurrent hemorrhage may include surgical clipping or endovascular coiling in the case of aneurysms and endovascular embolization, surgical resection, or treatment with stereotactic radiosurgery in the case of arteriovenous malformations. Supportive measures following any type of cerebrovascular insult include maintenance of cerebral perfusion pressure with intravenous fluids, avoidance of hypoglycemia or hyperglycemia, and avoidance of fever.

TREATMENT OF ISCHEMIC STROKE

Therapeutic as well as other strategies in the treatment and prevention of stroke has improved. The knowledge of role of inflammation and immune system in stroke and cerebrovascular disease has opened the door for research using *immunomodulatory* approaches in the treatment and prevention of stroke. There is only one Food and Drug Administration [FDA] approved treatment for ischemic stroke, the thrombolytic agent rt-PA that enhances brain reperfusion. Neuroprotective trials have been disappointing, with NXY-059—a free radical scavenger being the latest casualty [86-87; <http://www.astrazeneca.com>, 2007]. It is of note that a major limitation of hypothermia therapy for stroke, another form of neuroprotective therapy, has been the excess rate of pneumonic complications that has precluded its use, especially in the elderly. *Immune modulation* approaches would seem to be worthwhile pursuing based on the significance of the immune response on tissue and clinical outcomes after stroke. To date, therapeutic strategies for acute ischemic stroke have focused on preventing the recruitment and trafficking of neutrophils into ischemic lesions through inhibition of cellular adhesion molecules, however without success [88]. Enlimomab, a murine monoclonal antibody against ICAM-1, administered within 6 h of onset and continued for 5 days, led to worse stroke outcome: the antibody itself elicited a strong and adverse inflammatory reaction [89]. UK-279,276, an antibody that binds selectively to the CD11b/CD18 integrin on neutrophils was not effective in the Acute Stroke Therapy by Inhibition of Neutrophils [ASTIN] study [90]. It is possible that partial inhibition of neutrophils may be more effective than complete blockade.

Other *immune modulatory* approaches could theoretically include leukocyte-depleting strategies [not appropriate for the clinical population] and general strategies aimed at suppressing immune function [e.g., steroid treatment]: these have not proven to be effective in stroke and increase the risk of secondary infection. The antibiotic agent doxycycline appears to reduce leukocyte adhesion and was found to be beneficial in a temporary occlusion experimental stroke model, but has not so far been tested in the clinical setting [91].

Recombinant human interferon beta-1a [IFN-b1a] is an FDA approved treatment for patients with relapsing remitting multiple sclerosis. IFN-b1a inhibits pro-inflammatory cytokines and prevents BBB disruption and is currently being studied in ischemic stroke in a phase 1 safety study. This agent could lessen reperfusion injury after stroke [and possibly hemorrhagic transformation of infarcts which can be a complication of rt-PA therapy]. It too has been noted in a number of observational studies that patients who are taking a statin before a stroke have a better outcome than those who are not [92]. It has been proposed that, apart from cholesterol lowering, statins work through other mechanisms that include *immune modulation* [decreased inflammation], decreased oxidative stress, inhibition of the thrombogenic response and increased atherosclerotic plaque stability. In experimental stroke models statin administration has resulted in reduced size of brain infarcts [93].

TREATMENT OF HEMORRHAGIC STROKE

There are few proven treatments for intracerebral hemorrhage, the main management issue being strict control of hypertension. Surgical evacuation is usually reserved for

cerebellar hematomas, which show a mass effect [as clinically evidenced by a declining level of consciousness]. The coagulation factor Factor VIIa did show some initial promise in phase 2 studies [94] but was recently abandoned [<http://www.novonordisk.com>, 2007]. In terms of *immune modulation*, anti-inflammatory drugs such as COX-2 inhibitors, tacrolimus and fucoidan may reduce peri-hematoma inflammation and improve outcome in experimental stroke models [95]. Administration of the lipid-lowering drug atorvastatin has also been associated with improved outcome after experimental intracerebral hemorrhage, perhaps in part through modulation of inflammation in the peri-hematoma region [96]. For subarachnoid hemorrhage surgical clipping of the causative aneurysm or resection of the arteriovenous malformation is the mainstay of treatment. Endovascular coiling of the aneurysm can also be performed. Post-operative infection [either brain or respiratory] is an uncommon complication and not believed to be any more common than after other invasive surgical procedures. Hypervolemic-hemodilution and hypertensive [HHH] therapy is used to prevent spasm. There may be a role for anti-inflammatory measures for the prevention of vasospasm and delayed cerebral ischemia, as shown in a recent pilot study of patients treated with statins [97].

USE OF STEM CELLS IN TREATMENT CEREBROVASCULAR DISEASES

Stem cell therapy is an emerging therapeutic modality in the treatment of stroke. Its basis stems from the observation that certain parts of the adult brain are capable of regeneration [a relatively recent discovery]. Neurogenesis in the adult brain has been demonstrated in the dentate nucleus of the hippocampus and the subventricular zone. In a study of patients with ischemic stroke, neurogenesis was demonstrated in the ischemic penumbra, where cells were found to preferentially localize to the vicinity of blood vessels. These findings are suggestive of poststroke compensatory neurogenesis, which may contribute to recovery after the insult. While the regenerative capacity of certain parts of the brain has been demonstrated, it is clear that this endogenous repair process is unable to overcome the devastating damage to brain tissue that occurs after acute, severe stroke. Cell-based therapies have the potential to open up new avenues of treatment in this arena. Targets for stem cell therapy include neuroprotective approaches aimed at protecting at-risk tissue during the acute phase of stroke, as well as neuroreparative approaches which may involve direct replacement of damaged brain tissue, or alternatively promotion of the brain's endogenous repair processes. [98]

Stem cell-based therapeutics for stroke have recently commenced in the clinic [99]. Despite the advance in our scientific knowledge, cerebrovascular diseases are a major cause of death and disability worldwide. Accordingly, finding a novel treatment, which can be effective well beyond the acute 3-h window after cerebral attack, is being heralded as a unique treatment regimen in the clinic. In recent years, the advancement of stem cell therapy from the laboratory to the clinic has been guided by research recommendations from Stem Cell Therapeutics as an Emerging Paradigm for Stroke (STEPS) [100]. The consortium guidelines are designed to enhance the safety and efficacy of stem cellbased therapeutics as we translate these novel treatments to stroke patients. The endothelial progenitor cells can take advantage of STEPS as the cells move toward clinical application. Some evidence-based interventions during the acute phase of stroke such as organised stroke unit care and

reperfusion therapies with intravenous recombinant tissue plasminogen activator have been recognized to improve the outcome including survival and residual disability that are available only for a minority of patients [101].

Moreover, once cell damage from stroke is established, little can be done to restore pre-stroke conditions. In last years, in the background of this imperative clinical need, hundreds of studies have been published investigating therapeutic potential of stem cell transplantation, on the basis of animal studies showing that cells transplanted to the brain not only survive but also lead to functional improvement in different neurodegenerative diseases models [102].

Transplanted cells have been hypothesised to be effective not only by cell replacement within the damaged host tissue but also by providing trophic and neuroprotective support as well as immunomodulatory mediators [103]. The existence of endogenous neurogenesis in an adult vertebrate brain was described by Luskin et al. and Alvarez-Buylla et al., who demonstrated for the first time the presence of neuronal stem cells [NSCs] in the adult rodent subventricular zone [SVZ] that migrate out to the olfactory bulb and integrate into the existing neuronal network [rostral migratory stream, RMS] [104]. Recently, similar cell populations were identified in the adult human SVZ, with evidence of neurogenesis in the mammalian SVZ and subgranular zone of the dentate gyrus although the existence of the RMS still remains controversial in the human brain [105]. Recent studies have detected NSCs in other brain regions, such as the striatum, spinal cord and neocortex [106]. Interestingly, the stroke-damaged adult rodent brain preserves some replacement capacity mediated by endogenous NSCs. It is reported that stroke increases the number of newly generated cells in the SVZ in animals [107] and NSCs are able to generate new striatal neurons that migrate to the site of damage for several months after stroke [102].

Stroke infarct triggers early expansion of the progenitor pool increasing the fraction of proliferating SVZ cells and shortening the cell cycle length [108]. In addition to NPCs, stroke induces adult ependymal cells to proliferate and acquire features of radial glial cells [109]. Strikingly, stroke-induced neurogenesis has recently been observed in the adult human brain, even among the elderly [110]. Different neurotrophic factors [111] are responsible for endogenous neurogenesis stimulation after stroke. Moreover, neuroblasts migrate to the tissue adjacent to the infarct [112] attracted by matrix metalloproteinases [MMPs], particularly MMP2 [113], produced by the compromised endothelial cells and by neuroblasts themselves in a loop of endothelial–neuronal interaction. The neuroblasts protective role is reinforced by the fact that they express doublecortin, a marker of cell migration that is shown to be neuroprotective [113]. In addition, chemotactic signals, particularly SDF/CXCR4, are known to contribute to cell migration. There is also evidence of the beneficial impact of exercise on the functional plasticity after stroke, by providing neurotrophic support to the lesion environment and promoting neural repair. Exercise-induced neurogenesis was confirmed in humans by measuring exercise-specific changes in cerebral blood volume in the adult human dentate gyrus [114]. The majority of studies to date have shown relatively limited cell replacement from endogenous NSCs and mobilising endogenous NSCs is relatively a new approach.

In contrast, researchers has been in progress for decades to replace lost neural cells by transplantation of stem cells from different sources such as foetal embryonic stem cells, neuroepithelial or teratocarcinoma cell lines by using different methods for their isolation and culture. Potential advantages to this approach may include greater control over cell fate, the ability to deliver any desired number of cells and reduced risks associated with mitogen

infusion. The major goal is reconstitution of the complex and widespread neuronal–glial–endothelial interrelationship may require access to a broader array of cell lineages, since stroke affects multiple cell types including neurons, glia and endothelial cells. Thus, ideally, cells should need to maintain initially an immature state and differentiate into several specific cell types after engraftment. The host environment plays an important role in this issue by generating appropriate neurogenic signals. Lack of these may divert the cell fate predominantly toward the glial phenotype. Moreover, stem cell transplantation could enhance clinically valuable improvements through several other mechanisms, including growth factor production, endogenous damage-induced plasticity, and local re-innervation, partially due to neuronal replacement [Figure 1.4].

However, the potential success of transplantation in stroke, in comparison to neurodegenerative diseases, is influenced by some critical issues including anatomy, localization and size of infarct area, time of transplantation, vascular supplies, route and site of implantation and patient selection. Despite stroke injury being focal, the neuronal degeneration in stroke is not selective but involves different neuronal populations, including glial and endothelial cells, and disrupts various anatomical pathways, including both white and grey matter that need to be restored. In contrast, most experimental studies are conducted using a middle cerebral artery stroke model that presents mostly the striatum and, in a minor part, cortex damage, and only a few authors investigated cell therapy for cortex infarcts [115].

Abbreviations: UCB, umbilical cord blood; NSC, neuronal stem cell; BMMNC, bone marrow mononuclear cell; HSC, hematopoietic stem cell; MSC, mesenchymal stem cell. [Banerjee et al. 2012]

Figure 4. Stem cell types used in stroke trials and the proposed mechanisms of action.

Table 1.3. Summary of ongoing or completed [but unreported] acute/subacute stroke trials

Cell type	Study design	Expected no of patients	Timing of delivery poststroke	Route of delivery	Clinical trial identifier	Trial status
Acute and subacute trials (4 weeks postevent)						
BMMNC	PII, R-OL	120	7–30 days	IV	NCT01501773	Complete
MSCs	PII, NR-OL	120	7–14 days [infarct] or 10–21 days [ICH]	IV, then intrathecal 7 days later	NCT01389453	Recruiting
CD34+	PI/II, NR-OL	10	7 days	IA	NCT00535197	Recruiting
MSCs	PI/II, R-DB	78	,10 days	IV	NCT01091701	Not yet recruiting
MultiStem	PII, R-DB	140	1–2 days	IV	NCT01436487	Recruiting
ALD-401	PI/II, R-DB	100	13–19 days	IA	NCT01273337	Recruiting

Note: Multi-Stem and ALD-401 are commercially developed stem cell lines.

Abbreviations: BMMNC, bone marrow mononuclear cells; MSCs, mesenchymal stem cells; OECs, olfactory ensheathing cells; EPCs, endothelial progenitor cells; NR, nonrandomized; OL, open-label; PI and II, phase I and II trials; R, randomized; SB, single-blind; DB, double-blind; IV, intravenous; IA, intra-arterial; IC, intracerebral; ICH, intracerebral hemorrhage.

Thus, there are not any conclusive results on the possibility of restoring cortical damage and thereby memory and behavioural functions. It can be argued that infarcts associated with cortical involvement are larger and require the reestablishment of essential connections. The optimal time for cell engraftment after stroke is not yet well defined because of the dynamic modifications of the ischemic lesion's environment over time [116]. Excitotoxic neurotransmitters, free radicals as well as proinflammatory agents are released in acute phase [117]. The activated inflammatory response, leading to microglial reaction, together with apoptosis limits both the growth and survival of transplanted cells and endogenous neurogenesis [118]. Otherwise, the increased release during the stroke acute phase of cytokines and neurotrophic factors such as granulocyte colony stimulating factor [119] potentially could favour cell implant survival and growth. In experimental stroke, it has been observed that during the first 2–3 weeks and even longer, the peri-infarct cortex upregulates gene expression related to the modulation of neuronal growth, involving increased expression of cytoskeletal proteins, angiogenesis, cell proliferation, differentiation and migration from SVZ [120]. On the other hand, transplantation subsequent to the acute phase encounters difficulties due to the hostile lesion environment generated from the scar tissue formation. Stroke spontaneous recovery depends on brain's plasticity in terms of replacement of afferent and efferent connections and synaptogenesis, which occur early after stroke and last for months or years. There is evidence that these endogenous repair mechanisms can be enhanced by transplantation. In conclusion, it is rational to delay transplantation until neurological deficits reach a plateau and any further spontaneous recovery is unlikely. In studies seeking to demonstrate the generation of new graft-derived circuitry, even greater delays may be employed after injury to ensure stable long-term behavioural deficits prior to transplantation [120].

In conclusion, the field of cell therapy is a very exciting area to develop potential new therapies for stroke. However, the field is still too much in an embryonic and starting stage to make conclusions on its efficiency as a treatment for stroke. There are many unanswered questions surrounding the best cell types, optimal delivery routes, therapeutic time windows and appropriate patients.

STEM CELL THERAPIES FOR CEREBROVASCULAR DISEASES UNDER CLINICAL TRAILS

Routine use of stem cells at the bedside for stroke patients is an exciting prospect, though realistically remains a long way off. The future may well see the availability of “off-the shelf” stem cell products available for immediate use. Perhaps patients will receive individually tailored stem cell products, engineered to secrete specific trophic factors, to suit their specific subtype and duration of stroke. There is clearly a long way to go in both preclinical and clinical research, and long-term biosafety measures will be an essential consideration in this regard.

A number of clinical trials have now begun to demonstrate the safety and feasibility of different approaches to stem cell therapy. However, there are a large number of unanswered questions that remain. The great variation in the stem cell trials completed to date means that it is difficult to make any meaningful comparisons between them. Future clinical trials will need to start trying to address the important outstanding questions. It is imperative that trials are therefore designed with this in mind. Careful planning and collaborative work need to take place in order to maximize the likelihood of getting a useful answer from these studies. This includes such considerations as incorporation of a dose-escalation design and comparisons between different methods of delivery as well as different time points for delivery. The Stroke Therapy Academic Industry Roundtable [STAIR] II meeting elucidated the important considerations when designing future phase IIb studies. Many of these recommendations are particularly relevant to the field of stem cell research. They emphasized that “lack of establishing the optimal dose, duration of therapy, and time window may have contributed to the failure of neuroprotection trials.” Therefore, refinement and identification of the target population is essential. In addition, narrowing selection criteria in phase IIb studies to target patients more likely to respond based on clinical and imaging characteristics may optimize the chances of detecting a biologically relevant drug effect [STAIR IV recommendations]. Subsequent to these public cations, the Stem Cell Therapies as an Emerging Paradigm in Stroke [STEPS] meeting sought to develop a framework specifically to help guide design of future preclinical and clinical studies in the field of cell-based therapies. These recommendations from experts from the preclinical and clinical arenas should be carefully borne in mind before commencing any future trials.

In conclusion, there have been significant advances made in the field of stem cell research over the last two decades, with evidence of significant benefits in both acute and chronic animal models of stroke. Translation to clinical practice, however, remains a long way off. A number of trials are under way, though future work will need to concentrate on overcoming the still-significant challenges standing in the way of this becoming a realistic treatment option for the future.

ADVANTAGES OF STEM CELL THERAPY TO PATIENTS

A crucial question for upcoming clinical trials is which patients will benefit from stem cell therapy. The pathological type and anatomical location of the stroke are important issues, which are discussed in more detail below. In addition, demographic differences, in particular differences in age and gender, are also likely to affect how patients respond to treatment. The vast majority of preclinical work has been conducted on young, previously healthy, male animals. Elderly patients, who represent the largest subset of stroke victims, may not derive the same benefit as that seen in such animal studies. As stated previously, the majority of preclinical work has focused on ischemic rather than hemorrhagic strokes. In view of this, the ongoing and completed clinical trials have almost exclusively concentrated on ischemic stroke patients. Of the published clinical trials to date, only one has included any patients with hemorrhagic strokes [121].

Within the ischemic stroke subgroup, the majority of preclinical evidence for benefit has been obtained from animal models with predominantly striatal infarcts. A smaller number of trials have investigated cortical models of stroke, with mixed results [122]. Cortical strokes are associated with larger, more damaging infarcts, and it may be that these are too large to affect any repair. A direct comparison between subcortical and cortical infarcts in addition to various doses of cells would be useful in order to optimize patient selection. For example, one preclinical study that compared anatomical location found the benefit of stem cell therapy to be more pronounced in striatal infarcts, rather than larger cortical lesions [123]. Further issues to consider when designing clinical trials are stability of patients and associated comorbidities. Patients with larger strokes are commonly medically unwell due to multiple reasons [eg, aspiration pneumonia, cardiac arrhythmias], which could preclude them from entry into acute trials despite being eligible. Furthermore, multiple comorbidities are also likely to affect the response of the patient to stem cell therapy.

SUMMARY

Stroke is the leading cause of disability worldwide, the second most common cause of dementia and the third leading cause of death. It has enormous clinical, social, and economic implications and demands a significant effort from both basic scientists and clinicians in the quest for understanding the underlying pathogenic mechanisms, and thereby adopting suitable preventive measures and successful therapies. Once considered exclusively a disorder of blood vessels, growing evidence has led to the realization that the biological processes underlying stroke are driven by the interaction of neurons, glia, vascular cells, and matrix components, which actively participate in mechanisms of tissue injury and repair. Stroke is a serious neurological disease, and constitutes a major cause of death and disability throughout the world. The pathophysiology of stroke is complex, and involves excitotoxicity mechanisms, inflammatory pathways, oxidative damage, ionic imbalances, apoptosis, angiogenesis and neuroprotection. The ultimate result of ischemic cascade initiated by acute stroke is neuronal death along with an irreversible loss of neuronal function. Therapeutic strategies in stroke have been developed with two main aims: restoration of cerebral flow and the minimization of the deleterious effects of ischemia on neurons. Intense research spanning

over the last two decades has witnessed significant therapeutic advances in the form of carotid endarterectomy, thrombolytics, anticoagulant therapy, antiplatelet agents, neuroprotective agents, and treating associated risk factors such as hypertension and hyperlipidemia. However, the search for an effective neuroprotectant remains frustrating, and the current therapeutic protocols remain suboptimal. Till date only one FDA-approved drug is available for ischemic stroke; i.e., the serine protease tissue-type plasminogen activator [TPA], the utility of which is limited by the short therapeutic window. As new targets are identified, new opportunities emerge that build on an appreciation of acute cellular events acting in a broader context of ongoing destructive, protective, and reparative processes.

At the onset of the 21st century, it is the third-leading cause of death in most developed countries and the primary cardiovascular cause of death in Japan and China. The health burden of the disease is staggering as loss of a productive life inflicts a heavy toll on patients, families, and society. Yet this disease has no effective therapy beyond a limited group of patients [5%] who are treated with thrombolytics, which have significant adverse effects. This situation prevails despite intense research efforts and numerous clinical trials that have attempted to develop drugs to reduce morbidity and mortality from stroke. So far, drug development efforts have targeted modulators of ion channels [Ca^{2+} and Na^{+}], scavengers of oxygen radicals, and antagonists of excitotoxic neurotransmitters [primarily glutamate and glycine receptors].

However, current therapeutic strategies for stroke have been largely unsuccessful. One possible explanation is that research and pharmacological management have focused on very early events in brain ischemia. However, clinical trials with modulators of these targets have failed so far because of lack of efficacy, adverse effects, or other developmental difficulties. Debate on the reasons for this grim reality has sprung up in recent meetings, with finger-pointing about major possible causes of failure, including incorrect animal models, misidentified mechanisms of action, poor clinical designs, inadequate timing of treatment, and other variables. Moreover the brain ischemia and trauma elicit strong inflammatory reactions driven by both external and brain cells. The recognition of inflammation as a fundamental response to brain ischemia provides novel opportunities for new anti-inflammatory therapies. Two important pathophysiological mechanisms involved during ischemic stroke are oxidative stress and inflammation. Brain tissue is not well equipped with antioxidant defenses, so reactive oxygen species and other free radicals/oxidants, released by inflammatory cells, threaten the tissue viability in the vicinity of the ischemic core. With increase in our understanding regarding the roles infections and immune reactions play in the brain milieu this may also have an impact on the treatment of neuroinjuries and ancillary brain diseases.

Acute ischemic stroke is treatable, and our ability to treat patients with ischemic stroke continues to improve. Perhaps the most important has been the widening of the time window for both intravenous thrombolysis as well as endovascular arterial recanalization treatments. This change in the expansion of the time window has major implications because it could dramatically increase the number of potential patients for treatment. Further expansion of the time window is possible with the likelihood that imaging will provide the necessary information for identifying suitable, individual patients. The basic imaging approaches to acute ischemic stroke patients have evolved slightly since the first edition. More importantly, there has been a deepening of our understanding of the significance of the findings observed on standard and advanced diagnostic techniques like CT and MRI. Here we will focus on the

ischemic penumbra, and the other on how to use imaging to help guide endovascular therapy. All of this will reflect improved understanding of what imaging can provide the physician caring for the stroke patient to help make the wisest decision with respect to interventions that are being considered. The field continues to evolve, and better outcomes are possible and even likely. Indeed the burgeoning opportunities for treatment are so substantial that a major issue is whether there are enough trained physicians to provide optimal care to patients with acute ischemic stroke, especially those with the most severe strokes.

Cerebrovascular diseases are the leading cause of mortality and morbidity worldwide. These diseases pose many clinical challenges and even experienced clinicians can arrive at the point where work-up, treatment, or prognostic thinking falters. In the chapters coming ahead we will highlight the latest trends in preventive and treatment measures regarding patients prone to or suffering from stroke, embolism, thrombosis, hemorrhage, and other critical cerebrovascular ailments. While progress has been made in prevention and supportive care, efforts to protect the brain from cell death have not succeeded completely hence, no new treatment has made it from bench to bedside since tissue plasminogen activator was introduced some 18 years ago. Thus there is urgent challenge before the scientific fraternity to come up with new ideas and ways to treat stroke and protect brain from cell death. Most therapeutic approaches developed in the laboratory have focused on protecting neurons from the main pathogenic mechanisms causing ischemic injury, such as excitotoxicity, oxidative stress, inflammation or apoptosis. These experimental treatments have shown some progress in large clinical trials, an outcome that has sparked a lively debate about the promise of neuroprotection in stroke therapy. Unlike traditional therapeutic approaches based on counteracting selected pathways of the ischemic cascade, endogenous neuroprotection relies on coordinated neurovascular programs that support cerebral perfusion, mitigate the harmful effects of cerebral ischemia and promote tissue restoration. Understanding how the brain triggers and implements these protective measures may advance our quest to treat stroke and open a new era in stroke therapeutics. Here in this book we will describe different modalities by which the brain protects itself, aiming to provide a synthesis of the different mechanisms and highlighting their potential relevance for the future of stroke therapy. Leading-edge scientific research from across the globe and the possible mechanisms involved in treatment of stroke will be presented in this book to the audience. Finally we will focus on the role of different medicines and the natural herbs in the prevention and treatment of Cerebrovascular Diseases with focus on stroke.

ABSTRACT

The immune-privileged status of the CNS has evolved to maintain homeostasis required for neural function and host defense. The inability to generate robust and potentially harmful adaptive immune responses therefore requires a primary reliance for host defense on the sequestered and moderate innate responses of microglia, astrocytes, and other resident innate cells. Immunity and inflammation are key elements of the pathobiology of stroke, while the immune system participates in the brain damage produced by ischemia, the damaged brain, in turn, exerts a powerful immunosuppressive effect that promotes fatal inter-current infections and threatens the survival of stroke patients. Inflammatory signaling is instrumental in all stages of the ischemic cascade, from the early damaging events triggered by arterial occlusion, to the late regenerative processes underlying post-ischemic tissue repair. Recent developments have revealed that stroke, like multiple sclerosis, engages both innate and adaptive immunity. But, unlike multiple sclerosis, adaptive immunity triggered by newly exposed brain antigens does not have an impact on the acute phase of the damage. Nevertheless, modulation of adaptive immunity exerts a remarkable protective effect on the ischemic brain and offers the prospect of new stroke therapies. However, immunomodulation is not devoid of deleterious side effects, and gaining a better understanding of the reciprocal interaction between the immune system and the ischemic brain is essential to harness the full therapeutic potential of the immunology of stroke. Our understanding of the interactions between resident and peripheral immune cells, neurons, and glial cells and their implications for host defense, tissue repair, and neurodegeneration is still in its infancy. Increasing evidence shows that the central nervous system and the immune system interact in complex ways, and better insight into these interactions may be relevant to the treatment of patients with stroke and other forms of central nervous system injury. In

addition, the immune system actively participates in the acute pathogenesis of stroke. Thrombosis and hypoxia trigger an intravascular inflammatory cascade, which is further augmented by the innate immune response to cellular damage occurring in the parenchyma. The activation of innate immunity after stroke sets the stage for an adaptive immune response directed against brain antigens. The pathogenic significance of adaptive immunity and its long-term effects on the postischemic brain remains unclear. Further research will be required to determine what role, if any, immunity has in long-term outcomes after stroke, but elucidation of potential mechanisms may open promising avenues for the development of new therapeutics to improve neurological recovery after brain injury. Recent clinical and experimental studies have highlighted a complex role for the immune system in the pathophysiological changes that occur after acute stroke. Sensors of the innate immune system such as Toll-like receptors, or effectors such as the lectin pathway of complement activation and innate immune cells, are activated by brain ischaemia and tissue damage, leading to amplification of the inflammatory cascade. Activation of the adaptive arm of the immune system, mediated by lymphocyte populations including T and B cells, regulatory T cells, and $\gamma\delta$ T cells, in response to stroke can lead to deleterious antigen-specific autoreactive responses but can also have cytoprotective effects. Acute stroke is followed by a complex interaction between the brain and the immune system. Damage-associated molecular patterns are released after neuronal damage, and activate the innate and adaptive arms of the immune system. Different populations of lymphocytes can exert beneficial or detrimental functions after acute stroke, although the underlying mechanisms are not fully elucidated. Stroke can lead to immunodepression, increasing the risk of infections such as pneumonia. The increased incidence of infections is observed after acute stroke, and might result from activation of long-distance feedback loops between the CNS and peripheral immune organs, which are thought to play a part in stroke-induced immunodepression. Ongoing clinical trials are investigating whether the preventive use of antibiotics improves functional outcome after stroke. However, the delineation of the molecular interactions between the immune and nervous systems is proceeding rapidly and will yield translational application in the years to come.

BRAIN IMMUNE INTERACTIONS

To understand the fine-tuned bi-directional communication between the brain and the immune system is still a challenge for the Modern science. Brain-immune interactions take place in different organs, involving a wide range of cells and mediators, coordinated through sensory and effector pathways in the central nervous system [1-3]. The interactions work in both directions to maintain a healthy state of body and brain in the face of diverse, harmful challenges from injury, allergens, infective agents, foodstuffs and toxins. Dysfunction and inappropriate regulation of inflammatory or neuronal responses underlie many diseases that have become more prevalent in recent decades. Recent research has established a significant role for the immune system in several brain diseases including stroke, multiple sclerosis, tumors, mental disorders, Alzheimer's, and Parkinson's disease. In turn, mood disorders, stress, autonomic dysfunction, acute, and chronic brain injury have been linked with the development of organ failure, cancer, heart disease, systemic inflammatory conditions, infections, and hematological diseases further implicating dependent interrelationships between the immune system and the brain [4-8]. Both preclinical and clinical research has contributed significantly to our knowledge about these interactions, yet another major challenge is to translate multiple research findings into clinical benefit.

Murakami and colleagues present their research findings and their “gateway” theory of how regional neuronal responses can drive the migration of autoreactive T cells across the cerebrovascular endothelium to particular sites of the brain where they contribute to the development of experimental autoimmune encephalomyelitis (EAE), a mouse model of multiple sclerosis [9]. They also show that regional neural stimulation can therapeutically prevent the gating through blood vessels. Anrather and colleagues have described how reprogramming of local and systemic immune mechanisms contributes to the induction of cerebral ischemic tolerance, a process that is characterized by protection against the ischemic injury after application of ischemic stress to one tissue or organ [10]. Appropriate reprogramming of key immune mechanisms could be used to develop novel stroke therapies including possible prevention of injury through stroke in vulnerable individuals. The research paper by Denes et al., demonstrates that brain injury, anesthesia, and surgical interventions have diverse systemic consequences, including altered leukocyte responses in several organs of the body and rapid mobilization of granulocytes [11]. This could have important implications for animal models of cerebral ischemia as well as for patients with brain injury or for those undergoing surgeries or exposed to prolonged anesthesia. Assas and colleagues discuss important aspects of neuro-immune communication and show how sensory fibers containing the neuropeptide calcitonin gene-related peptide (CGRP) shape the responses of macrophages, mast cells and other immune cells throughout the body and how these interactions contribute to immune defense and diverse inflammatory conditions [12]. This neuropeptide and the c class nerve fibers that contain it thus form a key pathway for bi-directional neuroimmune interactions and could form a target for future neuroimmune based therapies. Neuro-immune processes are likely to contribute to diverse pathologies in both the periphery and the brain leading to complex human diseases that affect millions of people worldwide. Understanding mechanisms of neuro-immune interactions could help to find appropriate therapies to some of these conditions.

BRAIN-IMMUNE INTERACTIONS AND ISCHEMIC STROKE

Mounting evidence indicates that the immune system has a key role in brain injury. A better understanding of the interactions between the immune system and the brain can aid physicians who care for patients with stroke and other forms of central nervous system (CNS) injury. In addition, advancing our understanding of the immunology of stroke promises to generate novel clinical strategies, as well as diagnostic and therapeutic approaches. Here in this chapter we will discuss the selected aspects of the interactions between CNS injury and immunity, focusing on its implications for novel therapeutic agents to modify the immune response to stroke. In addition, we high-light the many gaps in our understanding of the role of the immune system in CNS injury and examine promising avenues of future investigation.

Immune system plays an elementary role in the pathophysiological progress of ischemic stroke. It consists of innate and adaptive immune system. Activated within minutes after ischemic onset, innate immunity is responsible for the elimination of necrotic cells and tissue repair, while it is critically involved in the initiation and amplification of post-stroke inflammation that amplifies ischemic damage to the brain tissue. Innate immune response requires days to be fully developed, providing a considerable time window for therapeutic

intervention, suggesting prospect of novel immune-modulatory therapies against post-stroke inflammation-induced brain injury. However, obstacles still exist and a comprehensive understanding of ischemic stroke and innate immune reaction is essential. In this chapter, we will try to highlight the current experimental and clinical data depicting the innate immune response following ischemic stroke, mainly focusing on the recognition of damage-associated molecular patterns, activation and recruitment of innate immune cells, and involvement of various cytokines. In addition, clinical trials targeting innate immunity were also documented regardless of the outcome, stressing the requirements for further investigation.

IMMUNE ACTIVATION AND THE RISK OF STROKE

Several lines of evidence suggest that activation of the immune system may increase the risk of stroke (Table 1). Numerous prospective population-based investigations demonstrated a correlation between levels of inflammatory biomarkers (such as white blood cell count, fibrinogen, D-dimer, and C-reactive protein) and the risk of incident and recurrent stroke [13]. Biomarkers may allow identification of patient subgroups who derive greater or lesser degrees of benefit from standard medications, such as antiplatelet or lipid-modifying agents. In addition, improved knowledge about the link between inflammation and stroke may lead to better and more timely recognition of specially vulnerable populations, such as patients with recent infection or surgery who face a transiently heightened risk of stroke.

Furthermore, animal models demonstrate that atherosclerosis has an inflammatory component, and inhibition of the immune response to lipoproteins seems to reduce the progression of atherosclerosis. These observations suggest that inflammation may have a causal role in vascular injury and subsequent stroke, which would open the door for immune-modulatory agents as new tools to prevent stroke in these patients. However, observational data are notoriously prone to confounding, and animal models often do not apply well to humans. Clearly, a more detailed understanding of the complex relationship between inflammation and stroke is required to better assess the feasibility of immunomodulation as a potential tool for stroke prevention.

Inflammation is increasingly recognized as a possible pathway in the pathogenesis of atrial fibrillation, which is a leading cause of stroke [14]. Levels of C-reactive protein are elevated in patients with atrial fibrillation and are associated with incident atrial fibrillation and with its recurrence after ablation or cardioversion. Inflammatory pathways may promote atrial fibrillation by interacting with cell signaling cascades, causing ion channel dysfunction, impairing myocyte gap junctions, promoting atrial fibrosis, and recruiting leukocytes to cardiac tissue. The relationship between inflammation and atrial fibrillation is most likely bidirectional, with atrial fibrillation causing some degree of immune activation and inflammation. The prothrombotic state seen in atrial fibrillation may reflect this inflammation, and anticoagulation with heparinoids seems to reduce biomarkers of inflammation in patients with atrial fibrillation. On the other hand, perioperative treatment with glucocorticoids reduces the incidence of atrial fibrillation after cardiac surgery, which suggests that inflammation may also have a causal role in the pathogenesis of atrial fibrillation. Once patients develop atrial fibrillation, their risk of stroke varies in proportion to known clinical risk factors, such as congestive heart failure, hypertension, age, diabetes

mellitus, prior stroke, and peripheral vascular disease. However, levels of the proinflammatory cytokine interleukin 6 are also associated with stroke risk, suggesting that inflammation is an additional biomarker of stroke risk within this population. Given these data, physicians should be mindful that periods of heightened inflammation (such as acute medical illness or recent surgery) place patients at higher risk of atrial fibrillation and stroke. With further development, biomarkers of inflammation may help to stratify patients' risk of developing atrial fibrillation and stroke, allowing targeted screening, risk factor modification, and timely treatment. A better understanding of the interactions among atrial fibrillation, inflammation, and thromboembolism may lead to the development of therapeutic agents that modulate inflammatory pathways to reduce the risk of atrial fibrillation and stroke.

IMMUNE SIGNALING DURING ACUTE INFARCTION

Besides its background role in stroke risk, the immune system actively participates in the acute pathogenesis of stroke [15]. Independent of any immune response, brain ischemia quickly causes failure of ion pumps, overaccumulation of intracellular sodium and calcium, loss of membrane integrity, and necrotic cell death. In addition, arterial occlusion immediately leads to intravascular hypoxia, changes in shear stress, and the production of reactive oxygen species, all of which in turn activate the coagulation cascade, complement, platelets, and endothelial cells. This results in a vicious cycle, with fibrin formation entrapping platelets and leukocytes and causing further vascular occlusion. In addition, oxidative stress reduces the bioavailability of nitric oxide, undermining its protective role in promoting vasodilation and inhibiting platelet aggregation and leukocyte adhesion, causing further vascular occlusion and ischemia. Central in this cascade of events is the translocation of P-selectin, an adhesion molecule whose expression on the surface of platelets and endothelial cells rapidly leads to cell adhesion. Trafficking of inflammatory cells into the perivascular space is facilitated by down-regulation of junctional proteins that maintain the integrity of the endothelial lining and the blood-brain barrier. Involvement of the perivascular space then activates resident macrophages and mast cells, leading to the release of vasoactive mediators and proinflammatory cytokines, which in turn recruit and promote the infiltration of more leukocytes. As cells die of ischemia, they release signals that further activate the immune system.

Extracellular accumulation of adenosine triphosphate released from dying cells activates microglia, which develop characteristics of macrophages and release proinflammatory mediators. Numerous normally intracellular components serve as danger-associated molecular pattern molecules on their release from dying cells, and these molecules activate toll-like receptors and scavenger receptors on microglia, perivascular macrophages, dendritic and endothelial cells, and infiltrating leukocytes. This activation induces the expression of proinflammatory molecules and primes dendritic cells for antigen presentation. Such proinflammatory changes are initially counterbalanced by the release of neurotransmitters, which activate anti-inflammatory receptors on microglia, and by the presence of cell-cell interactions between microglia and adjacent neurons, which usually keep microglia quiescent. However, as ischemic cell death progresses, neurons die and neurotransmitters are depleted, releasing this brake on proinflammatory signaling.

The clinical implications of the immediate immune involvement in the ischemic cascade are unclear. On the face of it, proinflammatory signals seem to promote microvascular occlusion and should tend to increase the size of the resulting infarct. In fact, in experimental models of stroke, mice deficient in adhesion receptors or complement subunits seem to be protected from acute ischemia, and healthy mice treated with inhibitors of adhesion molecules or the complement cascade also develop less ischemic brain injury. In addition, mice engineered to lack selected T-cell subgroups are protected from ischemic damage to the penumbral zone around areas of infarction [16]. Available data indicate that the protective effect of lymphocyte suppression does not stem from an inability to propagate thrombus and that no significant differences in cerebral blood flow exist between healthy and lymphocyte-deficient mice [17, 50]. It is possible that lymphocytes instead produce cell damage directly or through proinflammatory signaling and activation of downstream microglia and macrophages. Or, the early damage associated with lymphocyte infiltration of the ischemic brain may be due to the natural killer T-cell subtype that harbors a simplified T-cell receptor and may not require antigen processing. The available data do not provide a clear picture of how lymphocytes participate in acute infarction.

Clinical attempts to explicitly modify the immune response after stroke (such as trials of recombinant neutrophil inhibitory factor or antibodies against adhesion molecules) have been ineffective to date, and these failures highlight the complexity and redundancy of the pathways involved in the immune response to stroke. On the other hand, observational data and a randomized clinical trial indicate that acute use of statin medications at the time of stroke improves long-term outcomes and reduces mortality. Because this time window is not consistent with the lipid-lowering effects of statin medications, the benefit of their use during the acute stage of stroke has been attributed to their anti-inflammatory properties. This suggests that, despite the absence of specific clinical strategies or drugs proven to beneficially modulate immune functioning during acute brain infarction, further elucidation of this complex interplay may yield more sophisticated and pleiotropic therapeutics to augment the limited repertoire of antithrombotic agents available to physicians today.

Inflammatory Signaling in the Early Post-Ischemic Period

Post-ischemic inflammation is characterized by an orderly sequence of events involving the brain, its vessels, the circulating blood, and lymphoid organs. Inflammation is an integral part of the cascade of events triggered by ischemia and reperfusion (I/R) (Box 1). The inflammatory process begins in the intravascular compartment immediately after arterial occlusion, when the ensuing hypoxia, changes in shear stress, and production of reactive oxygen species (ROS) trigger the coagulation cascade, and lead to activation of complement, platelet and endothelial cells (EC) [18-21]. Intravascular formation of fibrin, traps platelets and leukocytes leading to microvascular occlusions and within minutes after ischemia, the adhesion molecule P-selectin is translocated to the surface membrane of platelet and EC12, and proinflammatory signals are rapidly generated (Table 1). Oxidative stress in EC reduces the bioavailability of nitric oxide (NO), a potent vasodilator and an inhibitor of platelet aggregation and leukocyte adhesion [22]. Loss of the beneficial effects of NO exacerbates intravascular plugging and aggravates the ischemic insult by reducing blood flow to the ischemic territory [23-24]. Furthermore, oxidative stress leads to constriction of pericytes,

contractile cells that replace myocytes in capillaries, producing microvascular occlusions [25]. Oxidative stress and inflammatory mediators also alter the permeability of the BBB. Pinocytotic vesicles increase in the cytoplasm of EC, enhancing trans-endothelial transport [26].

Proteases are expressed in vascular cells and released by leukocytes, whereas junctional proteins that seal adjacent EC are downregulated, facilitating extravasation of proteins and cells through the paracellular route (Figure 1) [26]. In the perivascular space, I/R activates perivascular macrophages and mast cells. Mast cell degranulation releases vasoactive mediators (histamine), proteases, and TNF, while activated macrophages release proinflammatory cytokines [27-29] (Box 2) (Figure 1). These proinflammatory mediators contribute to the endothelial expression of adhesion molecules and to the BBB damage that promotes the infiltration of leukocytes (neutrophils, lymphocytes and monocytes) [30].

Ischemic Cell Death Activates Innate Immunity and Sets the Stage for Adaptive Immunity

As the ischemic cascade progresses (Box 1), cell death leads to a new phase of the inflammatory response (Figure 2). Dying and dead cells release “danger signals” that activate the immune system. Some of these signals, like the nucleotides ATP and UTP, are released by cells under stress when the cell membrane is still intact and set the stage for the subsequent immune response [31-32].

ATP and Neurotransmitters

Extracellular ATP increases within minutes after ischemia as a result of neuronal and glial depolarization or escape through damaged plasma membranes. ATP is also released by vascular cells and blood cells, and may promote intravascular coagulation and platelet aggregation. High parenchymal ATP levels activate P2×7 receptors in microglia leading to release of pro-inflammatory mediators (Figure 2). Activated microglia develop many characteristics of macrophages including ameboid morphology, migratory capacity, phagocytosis and MHC class II-restricted antigen presentation (Box 3). At the same time, neurotransmitters release after I/R may counteract the emerging inflammatory response [33-35].

Microglia express a wide variety of neurotransmitter receptors, including AMPA, kainate, adrenergic, GABAB opioid, and cannabinoid receptors. With some exceptions activation of these receptors downregulates microglial cytokine, ROS and NO production, and suppresses the secretory response in mast cells [36-38]. Therefore, ATP represents an early neuronal danger signal, promoting the inflammatory response of resident immune cells, whereas neurotransmitter release may oppose these changes and counteract inflammation.

Box 1: From ischemia to infarction: The ischemic cascade

The brain is critically dependent on the continuous delivery of oxygen and glucose through blood flow, and interruption of the cerebral blood supply leads to irretrievable brain damage [Moskowitz MA et al 2010]. Ischemic damage results from a cascade of cellular and molecular events triggered by sudden lack of blood flow and subsequent reperfusion of the ischemic territory. Neurons are more vulnerable than glia and vascular cells, and when exposed to hypoxia-ischemia quickly become dysfunctional and die [Lipton P. et al 1999]. In ischemia produced by occlusion of the middle cerebral artery, the most common type of stroke, the damage is more rapid and severe in the center of the ischemic territory (ischemic core), where flow is lowest. At the periphery of the ischemic region, the so called ischemic penumbra, neuronal damage develops more slowly because blood flow arising from adjacent vascular territories (collateral flow) keeps cerebral perfusion above the threshold for immediate cell death [Moskowitz MA et al 2010]. In the ischemic core the major mechanism of cell death is energy failure. Without oxygen and glucose neurons cannot generate the ATP needed to fuel the ionic pumps that maintain the ionic gradient across the neuronal membrane, mainly the Na^+/K^+ ATPase [Lipton P. et al 1999]. Consequently, massive Na^+ and Ca^{2+} cytoplasmic accumulation leads to swelling and degeneration of the organelles, loss of membrane integrity and dissolution of the cell (necrotic cell death). In the ischemic penumbra, the flow reduction is not sufficient to cause energy failure, and neurons remain viable for a prolonged period of time after the insult. However, neurons are stressed and critically vulnerable to pathogenic events that may tip over their fragile metabolic balance. Excessive extracellular accumulation of glutamate is a major factor contributing to the demise of the ischemic penumbra. The resulting overactivation of the NMDA subtype of glutamate receptors leads to cytoplasmic accumulation of Ca^{2+} , which activates Ca^{2+} dependent enzymes, including the proteases calpain and caspase, and enzymes producing nitric oxide, free radicals and arachidonic acid metabolites. These events lead to necrosis or programmed cell death depending on the intensity of the insult and the metabolic state of the neurons [Lipton P. et al 1999]. Injured and dying cells play a key role in post-ischemic inflammation because they release “danger signals” which activate the immune system (see text).

The mechanisms of ischemic stroke have been studied using in vitro and in vivo models of cerebral ischemia. These models do not recapitulate all the features of human stroke and may introduce important confounders, such as anesthesia and surgical trauma. Furthermore, differences in vascularization and immune responses in the human brain (Box 2) may alter the initiation and evolution of the tissue damage. However, the core features of stroke pathophysiology are comparable between animals and humans and animal models of cerebral ischemia remain a mainstay of preclinical stroke research [Bacigaluppi M et al 2010]

Figure 1. Early vascular, perivascular and parenchymal events triggered by I/R Hypoxia, ROS and changes in shear stress initiate the cellular events induced by I/R. In the vessels lumen, I/R leads to blood clotting, platelet aggregation and cytokine release (IL-1 α). Translocation of P-selectin on the surface of platelets and EC leads to platelet-leukocyte aggregation. Complement is activated and arachidonic acid metabolites are released. In the vascular wall, upregulation of E- and P-selectin on EC provides a platform for low affinity leukocyte binding through interaction with sialyl Le^x moieties of glycoproteins expressed on leukocytes, e.g., PSGL-1. Firm adhesion is obtained after endothelial expression of ICAM-1 interacting with leukocyte β 2 integrins (LFA-1 and Mac-1. Loss of NO promotes vasoconstriction and enhances leukocyte and platelet aggregation. MMP activation could lead to BBB breakdown and matrix proteolysis facilitating leukocyte extravasation. In the perivascular space, chemotactic complement subunits (C5a) acting on mast cell complement receptors (CD88) leads to degranulation and release of histamine and proteases, contributing to BBB leakiness. Cytokines (TNF, IL-1 β) are produced by mast cells and perivascular macrophages, providing further signals to guide leukocyte migration across the vessel wall. In the brain parenchyma, injured cells release purines (ATP), which act as early proinflammatory signals leading to production of cytokines and chemokines. Disruption of neuronal-microglial interaction (CX3CL1, CD200) and increases in extracellular glutamate (glu) acting on microglial GluR1 metabotropic receptor also contribute to the pro-inflammatory milieu.

Box 2: Cells of the innate immune system

Cerebral ischemia engages both innate and adaptive immunity, the two main branches of the vertebrate immune system [Yilmaz G et al. 2006]. The innate system is germline-encoded, rapidly activated, and relies on low affinity receptors to gain wide-ranging target recognition. The adaptive system is based on high-affinity receptors, i.e., T-cell receptors and immunoglobulins, which are randomly generated by somatic mutations. In contrast to the innate system, adaptive immunity needs antigen-driven clonal cell expansion, a process that requires several days, and retains a memory of this antigen exposure [Yilmaz G et al. 2006]. Although specific cell types are predominantly associated with one of the two branches, there is considerable overlap between the role of these cells in innate and adaptive immunity. Here we describe cells predominantly associated with innate immunity. Lymphocytes are described in Box 3.

Microglia derive from the hematopoietic system and constitute the innate immune cells of the CNS [Ginhoux F, et al 2010]. Resting microglia survey the brain parenchyma through continuous extension and retraction of their processes [Nimmerjahn A, et al 2005]. Microglia contribute to post-ischemic inflammation by producing TNF, IL-1 β , ROS and other pro-inflammatory mediators. However, they also contribute to the resolution of inflammation and tissue repair by producing IL-10 and TGF- β , as well as several growth factors, including IGF-1 (Table 1).

Perivascular macrophages are confined to the space between the vascular basement membrane and the brain surface (glia limitans), and, unlike microglia, are continuously replenished by hematogenous precursors [Bechmann I, et al 2001]. Macrophages can be classified into two groups. M1 macrophages produce pro-inflammatory cytokines (IL-1 β , IL-12, IL-23 and TNF), chemokines, ROS, and NO, thus promoting a Th1 immune response (Box 3). In contrast, M2 macrophages produce anti-inflammatory cytokines (IL-10 and TGF- β), IL-1ra, and arginase [Mantovani A, et al. 2005]. After cerebral ischemia, cytokines produced by perivascular macrophages are thought to drive the infiltration of inflammatory cells [Konsman JP, et al 2007].

Mast cells (MCs) are found in meninges and cerebral blood vessels. MC granules store vasoactive substances (histamine), cytokines (TNF), anticoagulants (heparin), and proteases (tryptase, chymase, MMP2, MMP9) [Strbian D, et al. 2006]. In addition, MCs are capable of phagocytosis, antigen presentation and can modulate the adaptive immune response [Rao KN, et al. 2008].

Blood monocytes are direct precursors of tissue macrophages. At least two different monocyte populations have been described in humans and mice according to their surface markers and function. "Classical" monocytes produce the anti-inflammatory cytokine IL-10 when challenged with LPS, whereas "pro-inflammatory" monocytes produce TNF. After cerebral ischemia, inflammatory monocytes are rapidly recruited to the site of injury where they give rise to macrophages and DC [Tanaka R, et al 2003].

Dendritic cells are specialized APC and constitute the main interface between innate and adaptive immunity (Box 3). They originate from myeloid lineage through a common dendritic precursor [Geissmann F, et al 2010]. In the normal brain, DCs are associated with meninges, choroid plexus and the CSF. Cells expressing DC markers (CD11c⁺, MHC Class II⁺) appear in the brain parenchyma after focal ischemia and originate from resident, as well as blood borne cells [Reichmann G, et al 2002].

Neutrophils are secretory and phagocytic cells of the innate immune system and carry different types of cytoplasmic granules and secretory vesicles. Major pro-inflammatory molecules stored in granules and vesicles include, iNOS, NADPH oxidase, myeloperoxidase, MMP8, MMP9, elastase, and cathepsins. After cerebral ischemia neutrophils adhere to the cerebral endothelium and transmigrate into the tissue [Yilmaz G, et al 2010]. Vesicle and granule exocytosis is induced after receptor engagement, e.g. binding to E-selectin on EC, IL-8 stimulation [Borregaard N. et al 2010].

Is the immune system comparable in rodents and humans? Circulating neutrophils predominate in humans (50–70%), while lymphocytes predominate in rodents (75–90%). Several immune-related molecules, i.e., iNOS, P2 $\times$ 7, TLR2, antigen presenting proteins, co-stimulatory molecules, immunoglobulins, and chemokines, are differentially expressed in mice and humans, or present in one species and not the other [Mestas J, et al. 2004]. Human EC can present antigens to resting CD4⁺ and CD8⁺ T cells, while mice EC can only activate CD8⁺ T [Kreisel D, et al 2002]. Consequently, the immune responses initiated by vascular pathologies may differ quantitatively and qualitatively between humans and mice. The impact of these differences needs to be considered when transposing findings obtained from rodent models of cerebral ischemia to human stroke.

Cell Death and Pattern Recognition Receptors in the Post-Ischemic Brain

A different signaling landscape emerges after cells begin to die. A wide variety of molecular signals are released from the intracellular compartment or are generated by the action of lytic enzymes escaped from dead cells on matrix proteins (Figure 2). These so-called danger associated molecular pattern molecules (DAMPs) activate pattern recognition receptors (PRRs), including toll like receptors (TLRs) and scavenger receptors, widely expressed on microglia, perivascular macrophages, and brain EC [39]. DAMPs and purines act in concert to induce the expression of proinflammatory molecules in infiltrating leukocytes (Table 1) and to prime dendritic cells (DC) for antigen presentation (Boxes 2 and 3) (Figure 2). Considering the high vascular density of the brain, inflammatory mediators released from parenchymal cells are likely to feed back on the vascular and perivascular compartments to reinforce and amplify the expression of cytokines, chemokines and adhesion molecules that drive the infiltration of blood borne cells into the ischemic tissue. After neuronal death, loss of cell-cell interaction between neurons and microglia also promotes inflammatory signaling. In the normal state, microglia are kept quiescent by contact with neurons. For example, CD200, a surface protein expressed in neurons, interacts with its receptor CD200R on microglia enforcing a resting phenotype [40]. Disruption of this interaction due to postischemic loss of CD200 [41] may promote microglial activation (Figure 1). Similarly, CX3CL1 (fractalkine), a cell surface bound chemokine constitutively expressed by neurons, suppresses microglial activation through its microglial receptor CX3CR1. Thus, after neuronal injury loss of CX3CL1 results in enhanced microglial activation in several inflammatory disease models. In addition, increasing concentrations of extracellular glutamate activate metabotropic glutamate receptors on microglia leading to a proinflammatory phenotype [42-43] (Figure 1). Therefore, as neuronal death develops in the ischemic core and spreads to the penumbra the loss of the immunosuppressive effect afforded by neurotransmitter release and neuron-microglia interaction may also foster post-ischemic inflammation.

Collectively, these observations suggest that the inflammatory response after I/R starts at the vascular level, driven by non-transcriptional events triggered by hypoxia, shear stress and ROS production. As ischemia damages the brain tissue, danger signals are released first from cells under stress and then from necrotic cells. Concomitant with the loss of immunosuppressive mechanisms, these signals activate purinergic receptors and pattern recognition receptors, which induce an inflammatory response in resident brain cells and infiltrating leukocytes.

Release of nucleotides (ATP, UTP) from injured cells, including neurons, activates purinergic receptors on microglia and macrophages, and leads to production of proinflammatory cytokines. While most of these cytokines are transcriptionally induced, IL-1 β and IL-18 are processed from their pro-peptides by the activity of interleukin-1 converting enzyme (ICE; caspase 1). ICE is embedded in a multi-protein complex (NLRP3 or inflammasome) and is activated by microglial P2 $\times$ 7 receptor. Ischemic cell death leads to the formation of danger associated molecular patterns (DAMPs) molecules, which activate TLRs, especially TLR2 and 4. DAMPs released by ischemia include HMGB1, an intracellular DNA binding protein released after cellular injury, HSP60, and β -amyloid (A β), among others.

Table 1. Showing Mediators of post-ischemic inflammation and their producing cells

INITIATION non-transcriptional [cell type]	AMPLIFICATION Transcriptional [cell type]	RESOLUTION Transcriptional [cell type]
Cytokines: IL-1 β [MG, PVM, MC] IL-1 α [PLT] TNF [MC]	Cytokines: IL-1, IL-6, IL-10, IL-17, IL-20, TNF [EC, PVM, MG, AG, Neu]	Cytokines: TGF β , IL-10, IL-17, IL-23, [T cells, MG, Macr, AG]
Chemokines: CCL5 (RANTES), CXCL4, CXCL7 [PLT] CX3CL1 (Fractalkine) [Neu]	Chemokines: CCL2 (MCP-1), CCL3 (MIP- 1 α), CCL5 (RANTES), CXCL2/3 (MIP2), CXCL8 (IL-8) [EC, PVM, MG, AG, Neu]	Chemokines: NA
Adhesion molecules: P-selectin [EC, PLT]	Adhesion molecules: ICAM1, VCAM1, P-selectin, Eselectin, Mac-1, VLA-1, [EC, Leuk, PVM, MG, AG]	Adhesion molecules: BDNF, EPO, FGF, G-CSF, GDNF, HB-EGF, IGF-1, NGF, VEGF [MG, AG, PVM, Macr EC, Neu]

TLRs, in concert with scavenger receptors such as CD36, upregulate pro-inflammatory gene expression through the transcription factor NF- κ B30, DAMPs also derive from matrix breakdown by lytic enzymes released from dead cells and by the action of reactive oxygen species (ROS) on lipids. The cytokine production and complement activation resulting from these events leads to increased leukocyte infiltration and enhances tissue damage, which, in turn, produces more DAMPs. Antigens unveiled by tissue damage are presented to T cells, setting the stage for adaptive immunity.

Figure 2. Cell death and activation of pattern recognition receptors set the stage adaptive immunity.

Does a Classical Adaptive Immune Response Contribute to Ischemic Brain Injury?

Danger signals released from damaged cells also promote the presentation of tissue antigens that were previously hidden by the BBB or that develop as a result of the breakdown of cell membranes (Figure 2). Antigen presentation leads to the development of cellular and humoral immunity directed against the antigens (Box 3).

This adaptive immune response has the potential of inducing autoimmunity against the organ in which the cell death occurred, as described in the heart (Dressler's syndrome), eye (sympathetic ophthalmia) and pancreas (diabetes) [44]. Furthermore, the damaging effect of adaptive immunity is well established in MS and in models of autoimmune demyelination. The next section will review the evidence for a pathogenic role of adaptive immunity in stroke.

Box 3: The spectrum of lymphocyte subtypes

Lymphocytes are key cells in innate and adaptive immune responses. B-lymphocytes (B-cells) are responsible for humoral immune responses characterized by the production of antibodies that attack and neutralize specific antigens. T-lymphocytes (T cells) are involved in cellular immunity, in which extraneous antigens are suppressed by a cytotoxic cellular response [Abbas, Ak. 2010]. T cells express the glycoprotein CD4 or CD8 on their surface, a feature that determines their function and fate.

Antigen presentation

Central to adaptive immunity is antigen presentation, which is performed by APC, mainly DC and macrophage. APC patrol the environment and when they recognize a foreign antigen, a protein for example, they degrade it into peptides, some of which are then assembled with MHC class II molecules and displayed on the APC surface. The MHC-class II-antigen complex is recognized by the T-cell receptor (TCR) of CD4+ T cells, and this interaction in the presence of appropriate co-stimulatory molecules on APC (B7-1, B7-2) and T cells (CD28) results in T-cell activation [Greenwald RJ, et al 2005]. TCRs include either α - β chains or γ - δ chains, immunoglobulin-like proteins consisting of variable and fixed regions. After antigen presentation, CD4+ T cells undergo clonal expansion in lymphoid organs, a process promoted by autocrine production of IL-2 [Abbas, Ak. 2010].

Helper T cells

With notable exceptions, CD4+ T cells become helper T cells (Th), so called because they do not have cytotoxic function, but act as “helpers” by coordinating and modulating immune responses. Th cells include effector and regulatory cells. Depending on the molecular signals present in their milieu, different subpopulations of effector Th cells can develop, each characterized by a specific pattern of cytokine production. Th type 1 (Th1) effector cells secrete IFN γ and TNF and their development is promoted by IL-12 through the transcription factor t-bet. Th1 cells stimulate innate and T-cell induced immune responses leading to cytotoxicity. Th2 cells secrete IL-4, IL-5, IL-9, IL-10, IL-13 and promote humoral immunity, mucosal immunity, and responses directed against extracellular pathogens. IL-4 promotes Th2 cell development, which is regulated by the transcription factor GATA-3. Th $_{17}$ cells secrete IL-17 and their development is driven by TGF β and IL-6, and involves the transcription factor ROR γ t. Th17 cells participate in autoimmunity but have not been implicated in cerebral ischemic damage. Regulatory T cells (T $_{reg}$ or suppressor T cells) are either present naturally, or can develop from other Th subtypes in the presence of TGF β . T $_{reg}$ development requires the transcription factor FoxP3. Unlike other Th cells, T $_{reg}$ induce immunosuppression by producing IL-10 and TGF β [Wan YY. 2010]. Therefore, T $_{reg}$ are critical for the maintenance of the homeostasis of the immune system by counterbalancing the destructive effects of excessive inflammation and may play a protective role in cerebral ischemia (also see text).

Cytotoxic T cells

In contrast to CD4+ T cells, CD8+ T cells are cytotoxic. The TCR of CD8 expressing T cells binds the antigen presented with MHC class I molecules and co-stimulatory molecules. Unlike MHC class II, MHC class I molecules are present in every cell. After clonal expansion, activated CD8+ T cells patrol the internal environment in search of somatic cells expressing the antigens against which they were sensitized. Cytotoxic T cells kill somatic cells by permeabilizing the membrane with perforin and inducing apoptosis via granzyme-induced caspase activation or the Fas ligand pathway (Box 4). Lymphocytic cells with cytotoxic function also include natural killer (NK) cells and natural killer T cells (NKT). NK cells lack a TCR and, as such, do not require antigen presentation for their activation and cytotoxicity, which is triggered by interferons or cytokines. NKT cells have a simplified TCR that recognizes glycolipids presented by cells also expressing the MHC class I-like glycoprotein CD1 [Biron CA, et al 1999]. NKT cells exert their cytotoxic effect by releasing large amounts of IFN γ , IL-2, and TNF.

$\gamma\delta$ T cells

These are a subset of effector lymphocyte with a TCR comprising $\gamma\delta$ chains and particularly enriched in mucous membranes. Like NKT, these cells recognize non-peptide antigens and react to danger signals produced by stressed cells [Bonneville M, et al 2010]. $\gamma\delta$ T cells can exert different functions depending on the context in which they operate, ranging from cytotoxicity, to antigen presentation, immunoregulation, and production of growth factors [Hayday AC. 2009]. In cerebral ischemia, $\gamma\delta$ T cells have been implicated in both cytotoxicity and protective immunomodulation (also see text).

Stroke and Adaptive Immunity

Antibodies against CNS antigens develop after ischemic stroke, suggesting a humoral immune response to the injury, and circulating T cells become sensitized against CNS antigens, such as myelin basic protein (MBP) and related peptides. APC are reduced in the periphery and increased in the ischemic brain both in rodent and human stroke. The accumulation of APC coincides with the peak of lymphocytic infiltration and is associated with expression of MHC class II molecules and the co-stimulatory molecule CD80, findings suggestive of antigen presentation (Box 3). Support for involvement of adaptive immunity also comes from studies on the role of lymphocytes in models of focal cerebral ischemia. Ischemia leads to infiltration of the major lymphocyte subtypes into the ischemic brain (Box 3). Increasing evidence suggests that lymphocytes contribute to ischemic injury (Figure 3) [45-48]. Lymphocyte-deficient mice are protected from ischemic damage. The protection has been attributed to T cells, because B-cell deficient mice or lymphocyte-deficient mice reconstituted with B-cells are still protected from injury. $\gamma\delta$ T cells also have been shown to contribute to the injury by releasing the proinflammatory cytokine IL-17 (Figure 3). In contrast, T regs are protective in the late stage of cerebral ischemia, an effect evident only if the injury is small [49-51].

Additional evidence in favor of the involvement of cell-based adaptive mechanisms in stroke damage was provided by studies in which animals were tolerized against myelin-derived peptides (Table 2). Repeated mucosal administration of myelin antigens (tolerization) prior to arterial occlusion protects rodents from ischemic brain injury. Although tolerization is antigen specific, its beneficial effects are not restricted to immune responses directed at the inducing antigen, but are more widespread, a phenomenon termed bystander suppression [52].

The protection can be induced in naïve mice by adoptive transfer of splenocytes or CD4⁺ T cells from tolerized animals suggesting the involvement of cellular immune mechanisms [53]. Examination of T-cell function indicates that activation of tolerized T cells by the antigen unveiled by the stroke induces a Th2 cytokine response (Box 3). The effect has been attributed to IL-4 and IL-10 production that favors the formation of TGF β secreting Treg cells [54-56].

Other studies have found that administration of recombinant T-cell receptor ligand (RTL), consisting of α 1 and β 1 domains of MHC class II complex bound to a myelin peptide antigen (MOG35-55), reduces stroke volume in focal ischemia. The protective effect is associated with reduction of infiltrating inflammatory cells and may result from suppression of autoreactive T cells targeted against myelin. Although RTLs may not bind T cells, but APC and platelets, the findings suggest a role of cellular immunity in the mechanisms of ischemic brain injury [57-58].

Despite the evidence supporting an autoimmune response against the post-ischemic brain, there are inconsistencies with the hypothesis that classical adaptive immunity contributes to ischemic brain injury. The temporal profile of the involvement of T cells in brain damage is not consistent with established concepts of adaptive immunity (Figure 3). Thus, the protective effect observed in lymphocyte deficient mice or afforded by blocking postischemic trafficking of T cells into the ischemic brain occurs 24-48 hrs after ischemia, whereas adaptive responses require an interval of 7-10 days from antigen presentation to the clonal expansion of autoreactive T cells and immune attack on the target organ (Box 3) [59].

Figure 3. Deleterious and beneficial roles of T cells in stroke.

In the acute phase of cerebral ischemia, unprimed T cells contribute to tissue damage in an antigen independent manner (innate immunity), possibly through IFN γ and ROS (left upper quadrant). $\gamma\delta$ T cells, activated by IL-23 released from microglia/macrophages, produce the cytotoxic cytokine IL-17 and contributes to acute ischemic brain injury⁴¹. However, T cells can also be protective. TGF β produced by neurons, glia, or macroglia/macrophages promotes the development of Treg cells secreting the protective cytokine IL-10 and inhibits Th1 and Th2 responses. Treg cells are protective in models of cerebral ischemia. Induction of mucosal tolerance with CNS antigens produces an adaptive response, which leads to the establishment of autoreactive Th2 cells producing IL-10 and Treg cells producing IL-10 and TGF β ¹⁰⁷, is highly protective in experimental stroke (right lower quadrant). As discussed in the text, there is no evidence that adaptive immunity contributes to acute ischemic brain injury. However, weeks and months after stroke, autoreactive CD4⁺ and CD8⁺ T cells targeting CNS antigens could develop (right upper quadrant). The resulting cell death could play a role in the delayed brain damage and atrophy that occurs after stroke.

Furthermore, reconstitution of lymphocyte deficient mice with T cells targeting non-CNS antigens worsens ischemic damage, and mice lacking co-stimulatory molecules essential for antigen-specific T-cell response are not protected from ischemia. It is also surprising that unlike autoimmune responses in other organs, where there is a prevalence for either T-helper or T-effector cell participation, both CD4⁺ and CD8⁺ T cells are involved in ischemic injury [60]. Collectively, these observations argue against an autoimmune attack on the brain resulting from presentation of CNS antigen released by the stroke.

Box 4: How does inflammation work to kill?

ROS, NO, the complement system, apoptosis inducing receptors, and the perforin pathway represent the major effectors of cell death in inflammation.

ROS and NO

In the setting of inflammation, O_2^- is produced mainly by NADPH oxidase, an enzyme expressed in virtually all inflammatory cells (see box 2 and 3). At the same time, large amounts of NO are produced by de novo expression of iNOS. NO reacts preferentially with O_2^- to form the cytotoxic molecule peroxynitrite. H_2O_2 is derived from O_2^- dismutation and gives rise to the highly toxic hydroxyl radicals via the Haber-Weiss reaction, facilitated by the increased availability of free iron in ischemia [Selim MH, et al 2004]. These toxic molecules alter cellular proteins, lipids, and ribonucleic acids leading to cell dysfunction or death and have been implicated in the tissue damage produced by post-ischemic inflammation. For example, suppression of NADPH oxidase or iNOS activity protects the brain in the late phase of cerebral ischemia.

The complement system

The complement system is a proteolytic cascade composed of different subunits (C1 through C9) that leads to cell lysis via the formation of a pore like structure assembled from C9 termed the membrane attack complex (MAC). Complement also enhances phagocytosis (opsonization), or acts as a chemotactic-activating stimulus for inflammatory cells. The classical pathway for complement activation involves the interaction of the C1q subunits with immune complexes or IgM to activate the cascade. The lectin pathway utilizes mannose and N-acetylglucosamine-binding lectin to activate subunits C2 and C3, while the alternative pathway amplifies the C3 activity generated by the other pathways to form the MAC. After ischemia, complement is activated and its components are either upregulated in glia and neurons, or enter the brain through BBB breakdown [Yanamadala V, et al 2010]. The involvement of complement in ischemic damage is indicated by the fact that deletion of endogenous complement inhibitors increases brain injury, whereas their upregulation or administration is protective.

Apoptosis inducing receptors (Fas and TRAIL)

Fas (CD95), a member of the TNF-receptor superfamily, is expressed on neurons and glia after ischemia [Rosenbaum DM, et al. 2000], while its ligand FasL (CD95L) is present in neurons, microglia, cytotoxic T cells (CTL), $\gamma\delta$ T cells and NK cells [Strasser A, et al. 2009]. Fas ligation results in formation of the death inducing signaling complex (DISC) and subsequent activation of caspase-8 and of the pro-apoptotic factor Bid. Similarly, the TNF-related apoptosis-inducing ligand (TRAIL) is expressed de novo after ischemia in astrocytes and microglia, and induces apoptosis by engaging its receptors on neurons and glia. This pathway is involved in ischemic cell death because TRAIL inhibition or Fas mutation ameliorates ischemic injury [Cui M, et al. 2010 and Martin-Villalba A, et al 1999].

Perforin/Granzyme

This pathway is utilized by CTL, NKT, and NK cells and usually requires molecular recognition associated with MHC class I or class I-like molecules. After engagement of accessory surface receptors, e.g., ICAM-1, degranulation occurs releasing the protease granzyme, perforin - homologous to the complement subunit C9 - and the proteoglycan serglycin. This complex is internalized by the target cell, and granzyme triggers apoptosis by activating caspase-3 and Bid. The involvement of this pathway in ischemic brain injury is suggested by the observations that genetic deletion of perforin is protective [Liesz A, et al 2011].

The Lymphocyte Puzzle

If lymphocytes do not mediate an autoimmune attack on the brain how do they contribute to the early phase of ischemic brain injury? One possibility is that these cells participate in the cerebrovascular dysfunction occurring after ischemia or have prothrombotic actions leading to microvascular occlusions [61]. These effects would be deleterious by preventing reperfusion and by compromising collateral flow after I/R. However, lack of lymphocytes does not improve post-ischemic cerebral blood flow at least in the acute phase [62], nor does it suppress thrombus formation [50]. Therefore, effects of lymphocytes altering microvascular perfusion or patency seem unlikely. Another possibility is that NKT or $\gamma\delta$ T cells, T cells that have a simplified TCR and may not require antigen processing and MHC presentation, as well as NK cells (Box 3), are responsible for these early cytotoxic effects of lymphocytes. In support of this hypothesis, NKT cells are not present in Rag1^{-/-} mice and SCID mice [63] and they could contribute to explain the early neuroprotection observed in these models of lymphocyte deficiency [49-50]. However, CD1-deficient mice lack NKT cells and are not protected from ischemic injury at 24 hrs [50], suggesting that NKT cells may not be involved in the early phase of the injury. $\gamma\delta$ T cells have been implicated in ischemic brain injury, but their involvement seems restricted to the late phase of cerebral ischemia (4 days) [50-51].

Considering the limited number of studies available, the involvement of NK, NKT and $\gamma\delta$ T cells, lymphocyte subtypes that act in a fashion akin to innate immunity, needs further exploration. Collectively, these data suggest that, although an antigen specific immune response may develop following stroke, evidence that autoreactive T cells attack brain antigens exposed by ischemic damage against which they were sensitized is lacking. Lymphocytes do play a role in the development and progression of the injury, but the mechanism of their powerful effect does not conform to the tenets of classical autoimmunity. The role of NK, NKT and $\gamma\delta$ T cells, which could contribute to the acute phase of the injury, needs further exploration. Similarly, considering the evidence for humoral immune responses in stroke, the contribution of B-cells to the damage needs a more in depth assessment.

Resolution of Inflammation and Tissue Repair

Post-ischemic inflammation is a self-limiting process that eventually subsides and prepares the terrain for the structural and functional reorganization of the injured brain. The factors governing resolution of inflammation and the reestablishment of tissue homeostasis are still poorly understood, particularly in brain. Increasing evidence suggest that resolution of inflammation is not a passive process due to exhaustion of the signaling, but is orchestrated by the interplay of a large number of mediators which actively suppress the inflammatory response. Major steps in process include removal of dead cells, development of an anti-inflammatory milieu, and generation of pro-survival factors fostering tissue reconstruction and repair [64-65].

Clearing Dead Cells

Microglia and infiltrating macrophages constitute the predominant phagocytes which remove dead cells and tissue debris after stroke, a process orchestrated by “find me” and “eat me” signals. “Find-me signals”, including purines released from injured cells and chemokines, attract microglia and macrophages to the site of injury. These phagocytic cells are then presented with “eat-me signals” associated with dying or dead cells (Figure 4) [66-69].

TGF β , IL-10 and the Anti-Inflammatory Milieu

TGF β and IL-10 are pleiotropic immunoregulatory cytokines that play a crucial role in the development of the anti-inflammatory milieu associated with tissue repair (Figure 4). The production of these cytokines is promoted by phagocytosis and occurs in concert with the removal of dead cells [72]. TGF β is upregulated after ischemia primarily in microglia and macrophages and, in addition to its neuroprotective properties, has also profound effects on immune cells. Although well known for its proinflammatory effects, TGF β can suppress inflammation by inhibiting Th1 and Th2 responses and promoting Treg cell development [59]. Similarly, the immunoregulatory cytokine IL-10, produced by different cells including Treg cells [42], has both neuroprotective and anti-inflammatory activities (Figure 4). Therefore, postischemic production of TGF β and IL-10 can facilitate tissue repair by promoting the resolution of inflammation and exerting direct cytoprotective effects on surviving cells in the ischemic territory.

Growth Factors

Post-ischemic production of growth factors helps to establish an environment that is favorable to neuronal sprouting, neurogenesis, angiogenesis, gliogenesis and matrix reorganization [60]. Inflammatory cells, as well as neurons and astrocytes, are capable of producing a vast array of growth factors (Table 1). For example, microglia are required for the full expression of IGF-167, a critical factor in post-ischemic neuronal sprouting, whereas reactive astrocytes are required for functional recovery after stroke [73-75]. Vascular endothelial growth factor (VEGF), a key growth factor in post-ischemic angiogenesis, is produced by reactive astrocytes, and its action may require neutrophil MMPs, suggesting a link between inflammatory cells and angiogenesis [76-77]. However, VEGF administration early after ischemia or in excessive doses may enhance the damage [78-79]. The role that inflammatory signaling in brain recovery has also been highlighted by studies in which the transcriptome of sprouting neurons was defined indicating involvement of MHC I class molecules and complement subunits [74].

The evidence presented above indicates that cells of the immune system serve a fundamental role in all the phases of post-ischemic brain recovery. But, the limited data available provide only a glimpse into the complex sequence of events that reestablish the structural and functional homeostasis of the brain after stroke. Additional investigations on recently identified mediators instrumental to inflammation resolution and tissue repair, such

as lipoxins, resolvins, protectins, progranulins, and cyclopentenone prostaglandins (Table 1) (Figure 4), are needed to fully elucidate the role of the immune system in brain repair after stroke [64-65].

Figure 4. Resolution of inflammation and tissue repair.

Clearing of dead cells and suppression of inflammation are key events in brain repair. “Findme signals” (UTP, ATP) attract microglia and macrophages through P2Y2 receptors. “Eatme signals” include UDP, which act on P2Y6 receptors to stimulate microglial phagocytosis, and phosphatidylserine (PtdSer), which is translocated to the outer leaflet of the plasma membrane of apoptotic cells. PtdSer binding proteins involved in the clearance of dead cells include MGF-E8 on microglia and TIM4 on macrophages. Immunoglobulins directed against CNS antigens, which appear after stroke, may also promote phagocytosis by engaging Fc receptors on phagocytic cells. Phagocytosis promotes secretion of IL-10 and TGFβ56, which, in turn, suppress antigen presentation, promote Treg formation, inhibit expression of adhesion molecules in EC and production of proinflammatory cytokines. TGFβ and IL-10 are also neuroprotective¹, and may facilitate brain repair processes. In addition, arachidonic and omega-3 fatty acids metabolites lipoxins, resolvins, and protectins, which play an active role in the resolution of inflammation in other organs, could also contribute to suppress post-ischemic inflammation. Growth factors and MMPs produced by EC, neurons, astrocytes, oligodendrocytes and microglia are critical molecules driving tissue reorganization and repair.

Stroke and Systemic Immunity

Concomitant with the inflammatory response involving the brain, immunological changes are also observed in the blood, bone marrow, spleen and other lymphoid organs. Genome profiling of peripheral blood in stroke patients has demonstrated characteristic patterns of inflammatory gene expression that can help determine the cause of ischemic stroke, reflecting the specificity of the systemic inflammatory response to brain injury [80-81]. In rodent models as in patients with ischemic stroke, white blood cell count and expression of cytokines and inflammatory markers are increased within hours after ischemia. Such acute phase response is followed by a dramatic immunodepression, especially in patients with large strokes, characterized by lymphopenia, reduced functional activity of monocytes, upregulation of anti-inflammatory cytokines, lymphocyte apoptosis and splenic atrophy [82-84]. These immunological changes are associated with an increased tendency to respiratory and urinary tract infections, which are responsible for considerable morbidity and mortality in stroke patients. Infections tend to occur in patients with larger stroke and with low CD4 lymphocyte counts and elevated levels of IL-10 and IL-6, reflecting immunodepression [85].

How these systemic immune changes are mediated is not completely understood, but there is evidence that sympathetic activation and the attendant release of stress steroids and catecholamines are involved. Thus, cortisol and catecholamines are elevated in stroke patients most susceptible to infection, and steroid antagonists and the β -adrenergic receptor antagonist propranolol counteract post-stroke lymphocyte apoptosis and infection propensity in rodent models [86-87].

Bright and Dark Sides of Post-Stroke Immunosuppression

What is the biological significance of post-stroke immunodepression? One possibility is that the lymphopenia and immunosuppression limit the development of autoreactive T cells targeted to CNS antigens and dampen a potential autoimmune attack on the brain [88-89]. As discussed in the previous section the relative rapidity of the development of ischemic brain injury is not consistent with the temporal profile of an adaptive response against the brain.

However, it is conceivable that sensitization to CNS antigens plays role in the long-term outcome of the stroke (Figure 3). About 30% of stroke survivors have dementia, often associated with brain atrophy. The bases for the cerebral atrophy are not entirely clear, but immunological mechanisms triggered by the stroke cannot be discounted. Pathological studies have shown an inflammatory infiltrate that persists for years after the stroke.. However, these focal inflammatory changes have not been linked to poststroke immunosuppression or dementia, and their pathogenic significance remains uncertain. On the other hand, post-stroke immunosuppression is deleterious in that it increases the incidence of infections, a major determinant of poor neurological outcome, morbidity and mortality [88-89]. Acute infection could also negatively affect stroke outcome by upregulating costimulatory molecules and promoting antigen presentation. This possibility is supported by studies in which bacterial lipopolysaccharide (LPS) administered at the time of reperfusion to simulate post-stroke infection, worsens the outcome of experimental stroke and increases post-ischemic brain atrophy assessed 1 month after stroke. The effect is associated with increased expression of B7.1(CD80), a co-stimulatory molecule needed for efficient antigen presentation (Box 3), as well as T-cell sensitization against CNS antigens and a Th1 cytokine response [90-92]. Therefore, post-stroke immunosuppression is detrimental by increasing the incidence of systemic infections and, possibly, by promoting antigen presentation and autoimmunity against the brain, which may play a role in the long-term sequelae of the stroke. At the same time, immunosuppression could be beneficial by attenuating such delayed autoimmune response.

Bench to Bedside: Trials, Tribulations and Therapeutic Opportunities

Ischemic stroke remains an enormous therapeutic challenge. Currently, thrombolysis with tissue plasminogen activator (tPA) is the only effective therapy, but due to the narrow therapeutic window of less than 4.5 hrs and safety concerns, fewer than 5% of stroke patients receive this treatment (87). Among the potential therapeutic approaches targeting the ischemic cascade (Box 1), preclinical studies in rodent models suggest that suppression of inflammation offers unique advantages. First, these treatments have an extended therapeutic

window and are effective when administered up to 12–24 hrs after stroke [93]. Therefore, they could be used in patients who fail the time window for thrombolysis. Second, because suppression of inflammation is also beneficial in models of cerebral hemorrhage (90), concerns about worsening brain injury in patients in whom hemorrhagic stroke has not been excluded would be minimized and early treatment by emergency medical teams would become feasible. Finally, considering that the inflammation particularly deleterious in ischemia associated with reperfusion [94], suppression of inflammation would be a fitting complement to reperfusion therapy using thrombolytics or intravascular clot removal. Although these considerations are based on animal models, which may not recapitulate full in human disease (Box 1), inflammation is a critical pathogenic component of human stroke and remains an attractive target for therapeutic intervention.

Anti-Inflammatory Agents

Blocking antibodies directed against adhesion molecules (ICAM-1, MAC-1), or recombinant neutrophil inhibitory factor have not been effective in clinical trials. In the case of the ICAM-1 trial, the negative outcome has been attributed to deleterious immunoactivation resulting from administration of a mouse antibody to humans, as reproduced in an experimental study in which murine antibodies to rat ICAM-1 were administered to rats [95-96]. Although there also might be other reasons for these failures, a likely contributing factor is that post-ischemic inflammation acts through multiple redundant pathways that cannot be effectively suppressed by blocking a single cytokine or adhesion molecule, as attempted in these clinical trials. Thus, neutralizing upstream mediators of the signaling cascade or blocking multiple inflammatory pathways would be more effective. For example, blocking upstream components of inflammatory signaling, such as complement, TLR or scavenger receptors is highly protective in experimental models. Furthermore, minocycline, an agent with multiple neuroprotective actions including broad anti-inflammatory properties, has shown promise in clinical trials [97]. Another strategy, described in the next section, is to develop approaches in which the immune system is directed to suppress the deleterious effects of inflammation while enhancing its protective potential.

Immunomodulation and T-Cell Based Approaches

Ischemic tolerance provides an example of protective immunomodulation. Ischemic tolerance or preconditioning is a phenomenon in which a sub-lethal injurious stimulus protects an organ against a subsequent lethal stimulus. For example, a short non-damaging ischemic insult to the brain (local preconditioning) or other organs (remote preconditioning) protects the brain from a subsequent damaging ischemic insult [98-99]. Similarly, administration of low doses of LPS protects the brain from ischemic damage. Although ischemic tolerance is well known to protect the brain by simultaneously suppressing multiple pathways in the ischemic cascade [99], modulation of the post-ischemic immune response has emerged as one of its key effector mechanisms [100]. In the tolerance induced by LPS, post-ischemic TLR4 signaling is redirected towards production of IFN β , which, in turn,

reprograms the immune system to suppress the production of pro-inflammatory cytokines and the infiltration of inflammatory cells [101]. On the other hand, NF- κ B-dependent inflammatory mediators, such as IL-1, TNF, iNOS-derived NO and ROS, are also required for the full expression of the tolerance [99–102], indicating that the protection does not rely just on the suppression of deleterious inflammatory mediators, but on a fine balance between pro- and anti-inflammatory signaling. One of the challenges, therefore, is to learn how to modulate the immune system to replicate the beneficial inflammatory milieu induced by preconditioning. Tolerization may provide the opportunity to achieve this goal. Induction of immune tolerance through mucosal exposure to myelin antigens or E-selectin promotes a protective Th2 response, which acts through multiple pathways to suppress the deleterious effects of inflammation [55]. Due to the need to establish tolerization prior to injury, this approach, like preconditioning, would be more appropriate for stroke prevention in high-risk patients than acute stroke treatment. Another strategy is based on administration of RTL. As discussed in the section on adaptive immunity, RTL suppresses the infiltration of inflammatory cells and provides neuroprotection even if administered after the onset of cerebral ischemia [57]. Similarly, administration of the immunomodulatory co-polymer Poly-YE ameliorates neurological function without reducing injury volume, an effect attributed to increased production of growth factors and hippocampal neurogenesis [104]. The full translational potential of treatments based on immunomodulation has not been established. For example, therapeutic window, efficacy in females and in aging, protection in the presence of cardiovascular risk factors and efficacy in higher order species need further exploration. Nevertheless, its powerful protective effects justify additional investigations in this direction.

The recent identification of IL-17 secreting T cells as a critical effector of the tissue damage in autoimmune diseases (Th17 cells) and cerebral ischemia ($\gamma\delta$ T cells) [51] raises the possibility that counteracting IL-17 could be beneficial in cerebral ischemia as in experimental allergic encephalomyelitis [105]. Boosting the protective roles of Treg could also be beneficial [42], although a destructive role of these cells has also been proposed [106]. These approaches would be desirable because they target the delayed phase of the injury and are anticipated to have a particularly wide therapeutic window. However, as noted above the role of lymphocytes in ischemic injury is poorly understood and the full implications of suppressing the action of specific T and B-cell populations remain to be defined.

Fighting Inflammation: A Double-Edged Sword?

As discussed earlier in this chapter, immune cells and inflammation play an important role in tissue repair and reorganization. These beneficial effects have to be considered in developing therapeutic approaches based on restraining post-ischemic inflammation. The concern is that counteracting the inflammatory response to ischemic injury may ameliorate the tissue damage in the acute phase, but it may compromise repair mechanisms and worsen the long-term outcome of the injury. Due to the paucity of experimental studies in the recovery phase, there is no definitive experimental evidence that anti-inflammatory treatments interfere with repair processes in the post-ischemic brain. However, pro-survival effects of immune cells stemming from growth factor production, neurogenesis and neuroplasticity are well-established [106]. The essential role of inflammation in tissue repair highlights the difficulties with approaches based on full-blown suppression of inflammation.

Furthermore, in light of stroke-induced immunosuppression, the infectious complications of therapies suppressing inflammation also need to be taken into account. Therapies based on immunomodulation, in which the overall immune response is deviated from a Th1 to a Th2-type response, also have a dark side. In models of MS, tolerization with myelin antigens induces a protective Th2 response in the acute phase, but, in the long term, such Th2 response promotes B-cell differentiation and leads to a humoral attack against myelin which worsens the neurological outcome [107]. A similar worsening in the chronic phase has also been reported in tolerization applied to models of cerebral ischemia [108]. Therefore, the delayed effects of humoral immunity could counteract the shortterm benefit of suppression of cellular immunity. A more complete understanding of the immunology of stroke would enable the development of targeted approaches to selectively suppress the deleterious effects of inflammation.

The Role of Innate Immunity after Stroke

Ischemic onset is an insult for brain and immune system is firewall for the whole body. Immune system is divided into innate and adaptive systems. The innate immune system is the first line of defense, while immune system and central nervous system (CNS) were traditionally regarded as two distinct entities [109]. The existence of blood-brain barrier and absence of cerebral lymphatic vessels are largely impeding the communication between brain tissue and circulating immune cells and the antigen presenting T cells [110]. However, mounting evidence is challenging this viewpoint, indicating that ischemic stroke is complicated by mutual interplay between CNS and immune system. Innate immune response plays a dual role in stroke, exerting beneficial as well as deleterious effects on the outcome [111]. Considering the Yin and Yang effects of innate immune system, an overall suppression or activation of innate immunity might not be beneficial, while the true challenge is to selectively inhibit the deleterious effects without compromising the beneficial roles of innate immune response in tissue repair, remodeling, and recovery. It means that we should use immune system after stroke in the right time and right place.

Innate Immune System

Immune system monitors and preserves the homeostasis of CNS under normal and pathological conditions. Immune system consists of two mechanisms: the innate and adaptive immunity. The former reacts rapidly after ischemic insult and represents first step of inflammatory cascade [112], while the latter depends on antigen presentation and takes days to get activated. Therefore, innate immunity lays the foundation of the adaptive response and plays the key role in the integrated immune response secondary to cerebral ischemia. The innate immune system in the brain relies on various immune cells including resident cells such as microglia and endothelia, as well as circulating immune cells from blood such as neutrophils, monocytes/macrophages, and dendritic cells, among which microglia, neutrophils, and monocytes/macrophages are most investigated. Besides the cellular component, cytokines are also involved, mainly including interleukin- 1β (IL- 1β), interleukin-6 (IL-6), and tumor necrosis factor- α (TNF- α). Produced by immune cells, these cytokines

function to promote as well as quell inflammation, exerting both deleterious and protective roles. Immediately after cerebral ischemic onset, dying and dead neurons begin to release the so-called damage associated molecular patterns (DAMPs). Innate immune system senses the DAMPs via broad-specificity receptors and responds to the cerebral ischemic injuries within minutes, and the response remains predominant throughout the first few hours to induce postischemic inflammatory cascade (Table 2) [113].

Under normal condition, the blood-brain barrier forms a nature obstacle to prevent the entrance of circulating immune cells into the brain. However, under ischemic condition, necrotic tissues would cause local inflammation, leading to the release of inflammatory mediators like cytokines, chemokine, nitric oxide, and reactive oxygen species, which eventually leads to dysfunction of the blood-brain barrier, allowing the translocation of circulating immune cells [114].

Table 2. Showing activation and function of innate immune cells

Cell type	Activation time	Functions
Microglia	Within minutes	M1 phenotype promotes inflammation by secreting cytokines like IL-1 β , TNF- α and presenting antigens to T cell; M2 phenotype quells inflammation by secreting cytokines like IL-10, TGF- β , and tissue repair
Neutrophils	30 minutes	N1 phenotype exacerbates the damage, whereas N2 is protective
Dendritic cells	1 hour	Generally deleterious, suggested by researches to date
Macrophages	2 days	View point 1: M1 phenotype promotes inflammation and M2 phenotype quells inflammation (similar with microglia). View point 2: macrophages originating from peripheral monocytes are cytotoxic, while those from microglia are protective

The Role of Innate Immune System in Stroke

Initiation of Innate Immune Response: DAMPs and Pattern

Recognition Receptors

Neurons are particularly vulnerable to ischemic insult. Shortly after cerebral vascular accident, local ischemia would lead to the destruction of neurons in the ischemic core and peri-infarct zone, resulting in the release of various DAMPs including high mobility group protein B1 (HMGB1), uric acid, heat shock proteins, S100 proteins, DNA, and RNA, which attract and activate neighboring microglia and thereby trigger the postischemic inflammatory cascade. In spite of the mounting studies on DAMPs [115–116], it is still controversial which molecule represents the most important mediator that triggers the activation of innate immunity. Among all these DAMPs, high mobility group box 1 (HMGB1) stands out as the most investigated molecule [117]. HMGB1 is a nuclear protein normally localized in cell nuclei under the normal condition. Upon ischemia onset, however, neuronal necrosis causes the protein to translocate into the cytosol and then to passively enter the extracellular compartment. In clinical studies, Schulze and colleagues [115] detected an elevated plasma

HMGB1 level in patients with acute ischemic stroke and verified a correlation between HMGB1 level and circulating leukocytes. Release of HMGB1 by necrotic neurons in early stage of cerebral ischemia exhibits proinflammatory activity and amplifies inflammatory damage to brain tissue. Whereas intravenous injection of anti-HMGB1 monoclonal antibody would remarkably ameliorate brain infarction in middle cerebral artery occlusion models. Moreover, via electron microscopic observation, Zhang and colleagues [118] directly demonstrated that HMGB1 release induced rapid and drastic disruption of the BBB, followed by significant cerebral edema, which appeared to be in consistence with their findings by MRI. Interestingly, Hayakawa and colleagues [116, 119] found that, during the stage of stroke recovery, HMGB1 mediated beneficial plasticity and enhanced stem and progenitor cell recruitment, proliferation, and differentiation within damaged brain tissue.

HMGB1, as well as other DAMPs, is reported to induce downstream biological effects via interactions with pattern recognition receptors, including Toll-like receptors (TLRs), widely expressed on surrounding microglia, perivascular macrophages, and cerebrovascular endothelium [120]. The Toll-like receptor (TLR) pathway plays a pivotal role in the activation and amplification of innate immune response to endogenous tissue damage resulting from cerebral ischemia [121-122]. So far, 10 functional TLRs have been identified in humans as well as 12 in mice. TLR1-TLR9 are conserved in both species, while TLR 10 is not functional in mice because of a retrovirus insertion, and TLR 11, TLR 12, and TLR 13 have been lost from the human genome [123]. Among all the TLRs, TLR 2 and TLR 4 are expressed on the cell surface and detect endogenous ligands [124]. After middle cerebral artery (MCA) occlusion, TLR 2 and TLR 4 are documented to be upregulated and contribute to tissue damage by triggering the expression of inflammatory and apoptotic genes [125]. In fact, TLR 2 and TLR 4 play differential roles in acute cerebral ischemia/reperfusion injury. Hua and colleagues [126] found in genetic modified mice that TLR 4 knockout resulted in reduced infarct size, while TLR 2 knockout led to enlarged infarct size, higher mortality, and decreased neurological function, suggesting that TLR 4 contributed to cerebral ischemia/reperfusion damage, whereas TLR 2 appeared to be neuroprotective in response to cerebral ischemia. In addition to TLRs, the intracellular NOD-like receptors (NLRs) have also recently been identified as key mediators of inflammatory and immune responses [127]. NLRP 3 contributes to neurovascular damage by regulating the release of NLRP3-mediated proinflammatory mediators, and NLRP3 deficiency ameliorates cerebral ischemic injury in mice after by reducing infarcts and blood-brain barrier damage [128].

Activation of Innate Immune System

Activation of Local Resident Microglia in Central Nervous System

Microglia are the resident macrophages in brain that survey the CNS and eliminate debris via phagocytosis under normal and pathological conditions. In the resting state, microglia exhibit ramified appearance and once activated, these cells alter into an amoeboid morphology. Microglial activation is the initial step in CNS inflammation of numerous causes [129-130]. In ischemic stroke, microglia are activated within minutes of ischemic onset and microglial products are detected as early as 1 hour after stroke. Microglia express pattern recognition receptors including TLRs and NLRs to sense exogenous pathogens and endogenous danger signals [131].

Infiltration of Immune Cells from Peripheral Blood Monocytes/Macrophages Accumulation

Monocytes are resting innate immune cells derived from the blood. Upon activation, these cells would undergo morphological and functional alteration and then be referred to as macrophages. Of note, it has been controversial for years regarding the precise origin of local infiltrating macrophages [132], due to the morphological and functional similarity between activated microglia and recruited monocytes/macrophages. Once activated, microglia alter their morphology and gene expression to develop an inflammatory phenotype, making themselves indistinguishable to circulating macrophages [131]. Yet one mostly recent research has settled the debate, proving that local reactive macrophages consist of 2 distinct populations of cells, that is, a majority originates from resident microglia and a small group recruited from circulation [133]. In contrast to the immediate response of microglia, the latter group of cells is recruited no sooner than 2 days after ischemia and remains abundant through day 3 to day 7 [134].

Neutrophil Infiltration

Within the acute phase of ischemic stroke (minutes to hours), the injured tissue would release free-radicals and proinflammatory cytokines and chemokine, which would thereby upregulate adhesion molecules on endothelial cells as well as the surface of circulating immune cells, and facilitate the recruitment and migration of leukocytes [134]. Among all the components in the circulating immune system, neutrophils are the first responders [135] that are reported to react to the acute ischemia within 30 minutes and peak in the first 3 days [136]. Via neutrophil CD11b/CD18 and endothelial ICAM-1 interactions, neutrophils adhere to activated vascular endothelium and infiltrate into the injured area, and blocking of the interactions would result in reduced leukocyte accumulation [137].

Dendritic Cell Increment

As a link between the innate and adaptive arms of the immune system, dendritic cells (DCs) are key regulators in many forms of immune response [138], but the regulatory role of DCs in inflammation provoked specifically by stroke has not yet been sufficiently investigated. Kostulas and colleagues [139] stood among the first to provide data on DCs in cerebral ischemia and demonstrated ascending numbers of DCs in the ischemic hemispheres in rat models as early as 1 hour after permanent MCA occlusion. Later on, Gelderblom et al., [140] confirmed this finding by analyzing different subclasses of inflammatory cells using flow cytometric analysis and found in surprise that DCs showed one of the largest increases in cell numbers and accounted for a substantial portion among all the infiltrating immune cells with 20-fold increase on day 3 and still 12-fold on day 7. Consistently, a more recent study carried out by Yilmaz and colleagues [141] demonstrated in patients that the numbers of DCs decreased transiently after stroke; furthermore, by analyzing human cerebral specimens with acute ischemic or hemorrhagic stroke, the authors found numerous DCs locating in the infarct area, supporting the hypothesis that the DCs in circulation were most likely to be their recruitment into the infarcted brain. On the other hand, it is also possible that the part of the DCs found in the lesion originates from local cerebral cells such as microglia [139].

Dual Roles of Innate Immune System Cells

Microglia

Activated microglia function analogously to circulating macrophages, with the ability to eliminate necrotic tissue and secrete proinflammatory cytokines including IL-1 β and TNF- α under ischemic condition, which exacerbate brain damage and promote leukocyte infiltration [134]; on the other hand, these cells also exert a neuroprotective potential by releasing anti-inflammatory cytokines like IL-10 and TGF- β to quell inflammation and benefit the outcome [142]. In the emerging concept, microglia are assorted into M1 and M2 phenotypes, like macrophages. The M1 phenotype is referred to as the classically activated phenotype and processes deleterious features by secreting proinflammatory cytokines and presenting antigen to T cells, whereas M2 microglia, the alternatively activated phenotype, are involved in the neuroprotection and tissue repair after ischemic injury [131]. Existing data suggests that overall suppression of microglia fails to benefit experimental outcome but, on the contrary, results in larger infarctions and doubling apoptotic neurons after ischemia [143], indicating the significance of microglia in alleviation and recovery of injury.

Macrophages

Traditionally, macrophages are viewed as a noxious component that amplifies ischemic injury and exacerbates secondary progression of ischemic lesions. Monocytes/ macrophages are recruited via CCL2/CCR2 axis, and deletion of CCR2 or CCL2 results in smaller cerebral infarcts, reduced monocytes/macrophages infiltration, and less proinflammatory mediator production, indicating a deleterious effect of these cells [144]. But the majority of studies demonstrate that macrophages in the injured region, regardless of the exact origin, are polarized into M1 and M2 phenotypes, and the M2 phenotype would show beneficial effects against ischemic damage [130]. Girard and colleagues [145] reported that macrophages that originate from peripheral monocytes might be cytotoxic, independently of their phenotype, while microglia may be protective. On the other hand, Hu and colleagues [146] demonstrated that the majority of microglia/macrophages within the infarct areas experience an M2-to-M1 shift during the stroke progress. Soon after the ischemia, macrophages of the M2 phenotype were present and exerted neuroprotective effects; while being at the later stage of injury, the M2 phenotype gradually transforms into the M1 phenotype and is involved in neuronal damage.

Neutrophils

Although elevated neutrophil accumulation is often observed during cerebral ischemia/reperfusion, the exact pathogenesis role of neutrophil infiltration is uncertain, and blocking the postischemia neutrophil recruitment is not necessarily leading to improved outcome [135]. In current concept, neutrophils confer to a functional heterogeneity and polarize into 2 distinct subsets, in which N1 phenotype mediates deleterious effect, while N2 phenotype exhibits neuroprotective effects [51].

Dendritic Cells

To date the exact role of DCs was not defined comprehensively, but most studies suggested that DCs increment was associated with worsened outcome [139]. In murine models, the numbers of DC in the brain correlated with the size of the brain lesion after pMCAO [140], whereas in patients with transient ischemic attack, acute ischemic stroke, and acute hemorrhagic stroke, the extent of the decrease of DCs significantly correlated with the clinical stage and the radiological size of stroke [141]. Moreover, suppression of DC migration and maturation by granulocyte-colony stimulating factor contributed to attenuation of cerebral inflammation and reduction of infarct size, exhibiting neuroprotective effects in murine models of tMCAO [147].

The mechanism of how DCs lead to poorer outcome remained elusive. Theoretically, DCs presented in the infarcted areas may activate T cells, induce a long-lasting immune response, and therefore lead to further neurological damage [141]. Additionally, the transient decrease of circulating DCs might lead to immunodepression, resulting in poststroke infections to worsen the clinical outcome in stroke patients [140].

Cytokines

Infiltration and activation of innate immune cells result in the production of various cytokines and inflammatory mediators, which either exacerbate or alleviate inflammatory damage to the ischemic brain tissue. Within the first 24 hours of cerebral ischemia in animal models, inflammatory cytokines interleukin-1 β (IL-1 β), interleukin-6 (IL-6), and tumor necrosis factor- α are upregulated dramatically by up to 40- to 60-fold and are believed to affect the infarct volume and tissue damage. Therefore, these cytokines stand among the most investigated inflammatory mediators [147]. IL-1 β is one of the neurotoxic cytokines released within 30 minutes after ischemic onset. Activated microglia appear to be the major source, whereas other immune cells may also express IL-1 β . Noxious effects of IL-1 β are well documented in numerous studies [148-149]. It is considered as a neurotoxic mediator that directly induces neuronal death and enhances the expression of cytokines. Furthermore, chronic release of IL-1 β is associated with increased expression of adhesion molecules and blood-brain barrier permeability, promoting further leukocyte infiltration [150]. In animal experiments, IL-1 α and IL-1 β double knockout significantly reduced infarct volume in cerebral ischemic mice models [151-152]. Additionally, meta-analysis of animal model studies also revealed that IL-1 receptor antagonist markedly reduced infarct volume by 38.2% [153].

Expressed within the first hour after ischemic onset, TNF- α is also an essential component involved in the early stage of cerebral ischemia [154-155]. Increased TNF- α level in serum was observed after stroke in patients, and the increase correlated infarct volume and severity of neurological impairment. TNF- α plays a dual role in brain injury. The neurotoxic effect of TNF- α might be attributed to direct induction of neuronal death and indirect promotion of leukocyte infiltration by elevating the expression of adhesion molecules and chemokine. However, in addition to the deleterious roles, TNF- α also exerts beneficial effects and mitigates inflammatory injury. TNF receptor knockout was reported to be associated with enlargement of infarct volume. Besides, TNF- α pretreatment would result in decreased infarct volume and reduced leukocyte infiltration after permanent middle cerebral artery occlusion in mice [156].

Compared with the former ones, reports on the role of IL-6 in experimental ischemic stroke are relatively fewer [157]. And current available evidence argues against a pathogenic role of IL-6 in ischemic stroke. On the contrary, initial studies indicated that IL-6 deficient has no impact on infarct volume in mice models [158]. Whereas studies later on argued that the failure of IL-6 deficient to affect infarct size might be due to hypothermia in the mice models, and with well-controlled hypothermia, IL-6 deficiency would lead to increased infarct volume and neuronal death, suggesting a neuroprotective role of IL-6 [157]. Furthermore, underlying mechanisms of the neuroprotective potential of IL-6 are partially revealed in recent studies, in which IL-6 was demonstrated to participate in angiogenesis [159], and Jung and colleagues [160] verified that IL-6 exerted this ability and protected ischemic tissue probably via STAT3 pathway. Moreover, in order to depict the interactions between various cytokines participating the postcerebral ischemic inflammation, Zeng and colleagues [161] adopted Bayesian network (BN) learning procedure to explore the underlying links among circulating cytokines and discovered that IL-6 modulated TNF- α and IL-1 β mRNA expression directly or indirectly, indicating that IL-6 is a key mediator of the inflammatory cytokine network during the postcerebral ischemic inflammation.

Attempts and Difficulties in Bench-to-Bedside Translation

A better knowledge of poststroke inflammatory response may give birth to novel therapeutic strategies against ischemic stroke. Thrombolysis with rt-PA is the only effective treatment to date. However, due to the time window of 4.5 hours and safety concerns, the portion of stroke patients that would benefit from this treatment is less than 5%. On the other hand, immunomodulatory therapies hold a great potential. Based on current knowledge, inflammatory response reacts immediately after ischemic onset while requiring hours to days to fulfill. Therefore, immunomodulatory treatment would have extended therapeutic window. In addition, immunomodulatory therapy would not increase the risk of hemorrhage. Finally, since the inflammation would be particularly exacerbated upon reperfusion, immunomodulation would ameliorate the potential reperfusion-induced exacerbation secondary to medical intervention and recanalization [120].

As is mentioned above, poststroke inflammation is featured by significant leukocyte infiltration, which is facilitated by the upregulated adhesion molecules. Based on this theory, clinical trials are conducted to explore whether the suppression of leukocyte infiltration by blocking ICAM-1 with monoclonal antibody enlimomab benefits clinical outcome in acute ischemic stroke patients. Disappointingly, the clinical trial ended up with negative results, suggesting an even worsened outcome upon enlimomab treatment [162]. In this study, 625 patients with ischemic stroke were enrolled, of whom 317 were randomized to receive enlimomab within 6 hours after stroke onset. Patients were not enrolled if they had received rt-PA. The treatment lasted over 5 days. However, when evaluated at day 90, patients that received enlimomab exhibited significantly worse Modified Rankin Scale score and higher mortality. Additionally, patients in enlimomab group experienced more adverse events, primarily infections and fever, than the placebo group. The negative effect may be interpreted by the murine source of enlimomab and the murine antibody might activate neutrophils through complement-dependent mechanisms and therefore amplify the inflammation and damage [114].

Likewise, UK-279, 276, a recombinant glycoprotein that selectively binds to the CD11b integrin to reduce neutrophil infiltration and infarct size in murine models, failed to exhibit any

benefit in patients. The study was a multicenter, doubleblind, randomized, placebocontrolled clinical trial to evaluate the efficacy of UK-279,276 in acute ischemic stroke. 966 patients were enrolled, among whom 887 had ischemic stroke and 204 were cotreated with rt-PA. Unfortunately, the trial was stopped early for futility in both subgroups receiving UK-279,276 no matter with concomitant rt-PA prescription or not [163].

In addition to the above-mentioned immune cells and cytokines that complicate the immune response to stroke, free-radicals also complicate the pathophysiological progress [164-165]. Therefore, free-radical trapping agents like NXY-059 are theoretically neuroprotective, and this hypothesis was confirmed in animal models. Furthermore, SAINT I study [166] found that NXY-059 significantly reduced disability rate in patients receiving this agent and markedly lowered hemorrhagic risk in those receiving rt-PA concomitantly.

Nonetheless, the subsequent SAINT II study [167] overturned both of these optimistic findings, stating that NXY-059 was ineffective for the treatment of acute ischemic stroke and had no effect on the hemorrhagic risk of rt-PA. Since SAINT II study presented larger sample size (3306 versus 1699), it is reasonable to consider the results from SAINT II study to be more reliable and the data from SAINT I may be false positive. However, even though no evidence was found of an interaction between rt-PA use and the effect of NXY-059 in either trial, we cannot completely rule out the possibility that the disparity between the two trials may derive from the higher frequency of rt-PA prescription use in SAINT II study (44% versus 29%) in which maximal improvement may be achieved already by rt-PA, in spite of NXY-059 [167].

There are several promising findings as well. In another trial, investigators adopted IL-1 receptor antagonist (IL-1Ra) in attempt to block cytokine cascade. This randomized phase II study [168] recruited 34 patients, among whom half were randomized to receive IL-1Ra and the others received placebos. None of the patients received rt-PA. Upon 3-month evaluation, patients that received IL-1Ra exhibited lower levels of inflammatory markers and better clinical outcomes. No adverse events were observed in both groups. This study indicated that IL-1Ra was safe and well tolerated among acute stroke patients and that IL-1Ra held a great potential to be a novel therapy, whereas the efficacy required further investigation.

The trial and errors in the attempt to find novel therapeutic strategies targeting poststroke inflammation have revealed several obstacles before successful clinical translation were put forward by Macrez and colleagues [114]. Firstly, it is still uncertain whether animal models of stroke can recapitulate human pathology and predict success in clinical trials needs. Secondly, safety, tolerance, and potential adverse events associated with therapeutic immunomodulation are of relevant concern. Finally, our knowledge of immune system and stroke is still limited. The interactions between stroke and immunity are elusive, and the role of inflammation in ischemic injury is complicated and sometimes conflicting. Therefore, safe and successful bench-to-bedside translation calls for a more comprehensive understanding of immune response after ischemic stroke before it could benefit stroke patients substantially.

THE ROLE OF ADAPTIVE IMMUNITY AFTER STROKE

The inflammatory processes detailed thus far occur in a short time window after infarction and rely on the innate immune system, which involves the rapid activation of low-

affinity receptors that recognize a wide range of targets. The immediate onset of this inflammatory cascade and the available experimental data on patterns of signaling during early immune activation do not support a substantial role in this process for the adaptive immune system, which relies on the clonal expansion of specific lymphocytes with high-affinity receptors to specific antigens. However, the general immune activation caused by cerebral ischemia raises the questions of whether the adaptive immune system is eventually activated and how it may contribute to the propagation and repair of brain injury after stroke. After stroke, the number of antigen-presenting cells in the brain increases, along with costimulatory molecules required for antigen presentation to lymphocytes. This antigen presentation results in the production of antibodies against brain antigens and T cells sensitized to brain antigens. Furthermore, successive mucosal administration of myelin antigens in experimental models results in the development of immune tolerance and protection from subsequent ischemic injury, suggesting that this immune response involves adaptive immunity and that modulating it may be protective. On the other hand, although lymphocyte-deficient mice are protected from ischemic brain damage, reconstituting them with T cells directed against non-CNS antigens worsens ischemic damage. In addition, mice lacking the necessary costimulatory molecules for antigen-specific T-cell responses are nevertheless vulnerable to ischemic damage. Therefore, it is unclear whether the release and presentation of CNS antigens during and after stroke result in an adaptive immune response directed against the CNS.

If such an autoimmune response was directed against the brain after stroke, its long-term implications would potentially be significant. Such immune activity would be expected to impair neuronal plasticity and functional recovery and contribute to the frequent incidence of post-stroke dementia. Such concerns are supported by the presence of inflammatory infiltrates in damaged areas of the brain years after stroke, as well as by persistently elevated titers of antibodies to brain antigens. Abnormal permeability of the blood-brain barrier has been linked to the radiographic white matter changes frequently associated with vascular disease and cognitive decline, and levels of inflammatory biomarkers such as C-reactive protein are associated with white matter changes, lacunar strokes, and loss of microstructural integrity as measured by diffusion-tensor imaging [169].

Therefore, it cannot be discounted that immune activation contributes to the alterations in this endothelial permeability and vascular dysfunction. On the other hand, immune cells such as microglia may be important for clearing deleterious cellular debris that can cause neurodegeneration. Further research will be required to determine what role, if any, immunity has in long-term outcomes after stroke, but elucidation of any potential mechanisms may open promising avenues for the development of new therapeutics to improve neurological recovery after brain injury.

RESOLUTION OF INFLAMMATION AND THE ROLE OF THE IMMUNE SYSTEM IN TISSUE REPAIR

The inflammation unleashed by cerebral infarction is followed by a carefully orchestrated process to clear necrotic debris and foster tissue repair. This reparative process releases mediators that actively bring the inflammatory process to a close. Phagocytosis of dead cells

by microglia and macrophages promotes the production of immunomodulatory cytokines, such as transforming growth factor β and interleukins. Although transforming growth factor β has numerous proinflammatory effects, in this context it helps to suppress inflammation by inhibiting helper T-cell responses and promoting regulatory T-cell development. Interleukin 10 has neuroprotective and anti-inflammatory properties, and its release helps to facilitate the resolution of inflammation and promotes the survival of remaining viable neurons [170].

In this evolving process, the same cells that were initially recruited in the inflammatory phase serve as important sources of growth factors required for neuronal sprouting, neurogenesis, angiogenesis, gliogenesis, and matrix reorganization see Figure 5. For example, microglia are required for the full expression of insulin like growth factor 1, which promotes neuronal sprouting after injury. Reactive astrocytes produce vascular endothelial growth factor, which is required for angiogenesis. Circulating CD34⁺ immune progenitor cells promote revascularization in infarcted brain tissue. This reparative aspect of immune cells raises expectations that they can be harnessed to augment neuronal repair and recovery after CNS injury. However, experimental efforts so far provide cautionary tales; for example, increasing vascular endothelial growth factor levels early after ischemia or in excessive amounts actually worsens injury. Such findings highlight the complexity of the immuneresponse to CNS injury and indicate that attempts to modify these interactions must be undertaken with care.

Figure 5. Progression of inflammation and immune activation in the development of stroke.

Chronic inflammation from atherosclerosis, autoimmune disease, and physiological stress results in progressive vascular injury that increases the risk of stroke. Acute occlusion of the cerebral vasculature produces intravascular hypoxia that triggers a rapid inflammatory response. As tissue damage proceeds, cellular components activate the innate immune response and set the stage for the engagement of adaptive immunity. Questions remain about whether this immune activation after stroke causes autoimmunity that affects neurological recovery. CNS indicates central nervous system; LDL, low-density lipoprotein.

BRAIN INJURY AND IMMUNOSUPPRESSION

Thus far, we have focused on the effects exerted by the immune system on the CNS after stroke. However, this interaction is bidirectional, and CNS injury has profound effects on immune function. Within days of stroke, patients develop significant immunodepression, marked by lymphopenia, upregulation of anti-inflammatory cytokines, and splenic atrophy [171]. This immunodepression clinically manifests in the high rate of systemic infections seen in the immediate poststroke period. Patients with stroke are especially at risk of pneumonia and urinary tract infections, and such infections may independently worsen neurological outcomes and increase mortality. Immunodepression may account for the inability of other factors (such as dysphagia) to fully account for the high rates of pneumonia seen in survivors of stroke.

Poststroke immunodepression seems to be mediated by catecholamines and steroids released by sympathetic activation after stroke. Cortisol and serum catecholamine levels correlate with susceptibility to infection after stroke, and experimental models have shown that steroid and adrenergic antagonists counteract lymphocyte apoptosis and reduce rates of infection after brain injury. Intriguing clinical observations associate β -blocker use with lower rates of pneumonia and mortality after stroke, but given the sparse nature of these data and the pleiotropic effects of β -blockers, further research will be required to determine the usefulness of such widely available drugs to modulate the immune response after stroke.

Other efforts to counteract poststroke immunodepression have involved the prophylactic administration of antibiotics after stroke to protect patients from common infections. Several randomized trials investigated whether this strategy improves outcomes after stroke, and a meta-analysis of their results indicates that antibiotic use reduced the rate of infections but not mortality [170]. However, these studies were underpowered to detect a meaningful difference in mortality rates, and further large trials will be required to answer this question. If antibiotic use is eventually shown to improve outcomes after stroke, questions will remain about the effects of such a strategy on microbial resistance patterns. Nevertheless, it is possible that a strategy of prudent poststroke antibiotic use may emerge as a cost-effective and safe strategy for improving outcomes in these vulnerable patients. In the meantime, physicians should be cognizant of the immunosuppressed state of their patients with stroke and should remain vigilant to expeditiously identify and appropriately treat infections in these patients.

RELATIONSHIP BETWEEN POSTSTROKE IMMUNODEPRESSION AND ADAPTIVE IMMUNITY

In speculating about why poststroke immunodepression occurs, on the surface it would seem to harm patients by increasing their risk of infectious complications. Although it may simply be a maladaptive response that stems from inherent aspects of the design of the CNS and immunesystem, immunodepression may serve to protect the CNS from the development of adaptive immune responses directed against self. Recent data indicate that the CNS undergoes regular immune surveillance by circulating lymphocytes. Central nervous system components are not routinely presented to these lymphocytes in such a way as to sensitize them and launch an immune response against the CNS. However, in the absence of

countervailing factors, such antigen presentation would be expected to occur after CNS injury and compromise of the blood-brain barrier. Therefore, the immunodepression seen after stroke may serve a beneficial purpose in limiting the development of such autoimmunity. Such considerations suggest that a detailed understanding of the many facets of the interactions between the CNS and the immune system is needed to guide any interventions to modify these interactions and improve outcomes.

IMMUNE RESPONSE TO ACUTE STROKE

Traditionally, several obstacles to a full immune response have been thought to exist in the CNS. These obstacles include the blood-brain barrier (BBB), the lack of cerebral lymphatic vessels, the apparent inefficiency of microglia and astrocytes for antigen presentation to T cells, the high rate of apoptosis in cells that cross the BBB, and the influence of contact-dependent or contact-independent mechanisms between neural cells that downregulate the crosstalk of these cells with lymphocytes and other immune cells [171-175]. Recent data, however, have dramatically altered this viewpoint by revealing that the CNS actively interacts with the immune system, both directly and via intermediates [176-177].

Mounting evidence indicates that acute stroke is followed by a complex interplay between the CNS and the immune system. The concentration of various cytokines is increased in the cerebrospinal fluid and blood of patients with acute stroke, and these changes are associated with clinical events including infection, functional outcome and mortality [178-180]. In this section, we will discuss the recent clinical and experimental studies on the innate and adaptive immune responses following acute stroke, including cytotoxic and cytoprotective effects, and the role of stroke-induced immunodepression in increasing the risk of infection. It is suggested that a better understanding of these findings could promote the identification of novel therapeutic targets for this devastating condition.

Innate Immune Response after Stroke

Phylogenetically, innate immunity is the oldest system of host defence and provides the early response against microbes and products of injured cells. It consists of physical and chemical barriers, cellular components such as macrophages, neutrophils and natural killer cells, blood proteins such as members of the complement system and mediators of inflammation, and cytokines, which are important regulators of the immune response (Figure 5).

Damage-Associated Molecular Patterns

Acute stroke stimulates an inflammatory cascade in the occluded vessel, the arterial wall and the brain parenchyma.¹¹ Destruction of neural cells leads to release of damage-associated molecular patterns (DAMPs) to the extracellular environment, which activate the innate and adaptive arms of the immune system and further stimulate the inflammatory cascade [181-

182]. Neurons are particularly vulnerable to ischaemia, and rapidly release DAMPs that attract and activate neighbouring microglia. DAMPs include the chromatin-associated protein termed high mobility group protein B1 (HMGB1), uric acid, heat shock proteins, ATP, S100 proteins, heparan sulphate, DNA, and RNA [183-184].

The release of DAMPs can be associated with either beneficial or harmful effects: inhibition of HMGB1 was neuroprotective in several experimental studies, whereas application of HMGB1 promoted functional recovery. Administration of uric acid was shown to be neuroprotective after experimental transient focal brain ischaemia, and higher endogenous levels of uric acid were associated with more-effective reperfusion therapy in patients with acute stroke. By contrast, reduction of the level of uric acid was associated with attenuated neutrophil recruitment to the liver after acetaminophen-induced liver injury. A possible explanation for the organ-specific effects of uric acid in these studies is that the brain has a considerably lower endogenous antioxidant capacity than does the liver, which could cause the antioxidant capacity of uric acid to prevail over its proinflammatory effects in the brain but not in the liver [185-187].

Innate Immune Receptors

Innate immune cells sense exogenous pathogens and endogenous danger signals through pattern recognition receptors that include Toll-like receptors (TLRs), RIG-1-like receptors, NOD-like receptors, C-type lectin receptors and AIM2-like receptors [188]. These receptors activate downstream signalling pathways, such as nuclear factor- κ B, mitogen-activated protein kinase and type 1 interferon pathways, which in turn upregulate proinflammatory cytokines, chemokines, reactive oxygen species, and costimulatory signals. Activation of these receptors also promotes priming, activation and clonal expansion of antigen-specific T cells. The importance of these receptors in mediating tissue damage in stroke was highlighted in studies that showed smaller infarcts and less-severe brain haemorrhages in transgenic mice lacking TLR2 or TLR4 than in wild-type mice. Moreover, a better outcome was observed in patients with stroke who exhibited reduced expression of TLR4 in monocytes [189-192].

Monocytes

Monocytes are multifunctional innate immune cells with crucial roles in the regulation of inflammation and tissue repair. In rats, monocytes were found in the damaged brain tissue shortly after acute stroke. In patients with acute stroke, these cells increased in number in the blood, and showed phenotypic changes comprising reduced expression of antigen-presenting molecules and low production of proinflammatory tumour necrosis factor, although production of anti-inflammatory IL-10 remained unchanged. The magnitude of these changes was associated with the risk of poststroke infection, whereas the balance between classic CD14⁺ proinflammatory monocytes and minor populations of reparative CD16⁺ monocytes was associated with stroke outcome. These monocyte subtypes could represent populations of cells that differentiate into M1 and M2 macrophages, respectively. M1 macrophages promote strong T-helper-1 (TH1) responses, whereas M2 macrophages support TH2 responses and might play a part in resolution of inflammation [193-197].

The Complement System

The complement system is part of the innate immune response, and its activation has been described in clinical and experimental stroke. The lectin pathway of complement activation is initiated by mannose-binding lectin (MBL) and MBL-associated serine proteases. Patients with stroke who have an MBL low genotype express lower levels of the complement components C3, C4, and C-reactive protein, and have better functional outcomes than patients with an MBL-sufficient genotype. Similarly, following brain ischaemia, transgenic mice lacking MBL show reduced infarct size, C3 deposition and neutrophil infiltration, and better outcomes than do wild-type mice. Together, these findings emphasize the clinical relevance of this component of the innate immune response after stroke [198-200]

Adaptive Immune Response After Stroke

Adaptive immunity is an evolutionary advancement that provides more-effective defence mechanisms against microbes and injured cells than does innate immunity. The adaptive response is slower than the innate response but has exquisite specificity for a large number of microbial and nonmicrobial substances. This arm of the immune system also has the capacity to 'remember' previous exposure to a given pathogen and mount a more rapid response on repeat infection. The main cellular components of this response are B and T lymphocytes, secreted products of these cells such as antibodies and cytokines, antigen-presenting cells, and effector cells. The adaptive response is initiated by recognition of antigens by lymphocytes, which respond by proliferating and differentiating into effector cells that can have cytotoxic or cytoprotective effects (Figure 5).

Cytotoxic Effects

Effector T Cells

Recent experimental studies suggest that different T-lymphocyte subpopulations, but not B cells or natural killer cells, are involved in the evolution of brain infarction and accompanying neurological deficits. During the early phase of stroke, T cells cannot cross the BBB, and probably exert their detrimental effects independently of antigen recognition.

The invasion of lymphocytes into the brain parenchyma is regulated by interaction of the leukocyte-expressed very late antigen with endothelial vascular adhesion molecule 1. The extravasation of lymphocytes to the brain parenchyma is facilitated by oxidative stress, by proteases expressed in vascular cells and released by leukocytes, and by other inflammatory mediators that contribute to alteration of BBB permeability. Infiltrating T cells are the main source of IFN- γ , which mediates delayed neurotoxic effects in the ischaemic brain tissue [201-202].

$\gamma\delta$ T cells and the cytokines IL-23 and IL-17 seem to have a crucial role in maturation of brain infarction. Activation of $\gamma\delta$ T cells does not require stimulation of the antigen-specific T-cell receptor, and is probably induced by IL-23 secreted by infiltrating macrophages, and by activation of surface TLRs, such as TLR2 via DAMPs (discussed above). In a mouse model of stroke, activated $\gamma\delta$ T cells infiltrated the brain and in turn produced the

The diagram illustrates the pathogenesis of stroke and the role of the immune system. It is divided into three main regions: Cerebrospinal fluid (top), Brain tissue (middle), and Blood vessel (bottom). Stroke is indicated by lightning bolts on the left. In the Cerebrospinal fluid, Cerebrospinal fluid drainage is shown. In the Brain tissue, Neuronal death leads to Antigen release and DAMPs, which activate microglia. Resting microglia also become activated. Oxidative stress (O_2^-) leads to Inflammation. In the Blood vessel, BBB damage leads to Complement activation (C5b-2) and Blood clotting. Leukocyte infiltration occurs from the blood into the brain tissue. The diagram also shows the activation of T cells (Activated T cell) and the role of the Cervical lymph node (Activated B cell, Activated T cell, Soluble antigen, Antigen recognition). The final outcome is Tolerance or damage, leading to Lymph and Blood flow.

Brain ischaemia triggers a complex cascade of events that include oxidative stress, microglial and complement activation, blood clotting, vascular damage, cellular infiltration of the ischaemic tissue, and activation of the innate and adaptive immune systems. DAMPs released by necrotic cells are sensed by pattern recognition receptors such as Toll-like receptors, which are expressed by immune cells and neural cells. The adaptive immune system is also stimulated by damaged brain cells through the release of brain antigens that drain to peripheral lymph nodes and encounter antigen-presenting cells, and T and B cells. This encounter can cause a T-cell-mediated reaction in the brain, and can lead to generation of antibodies against specific brain-derived molecules. Whether these effects cause autoimmunity or facilitate induction of tolerance has not been fully elucidated. Abbreviations: BBB, blood–brain barrier; DAMPs, damage-associated molecular patterns; T^{REG}, regulatory T.

Invasion of lymphocytes after acute stroke can expose brain epitopes that are normally ‘hidden’ from the immune system, and can promote priming and activation of lymphocytes that are reactive to CNS antigens. Lymphocytes that are specific for CNS antigens could boost inflammatory responses in the damaged brain tissue, thereby contributing to a worse

stroke outcome. Some patients with stroke show higher serum antibody titres and numbers of circulating T cells specific for CNS antigens than do healthy controls, suggesting that the inflamed CNS tissue induces self-directed immune responses [210-211]. The emergence of autoreactive immunity after stroke was also suggested by recent studies that found an increased presence of neuronal and myelin antigens in the cervical lymph nodes and palatine tonsils of patients with acute stroke. The antigens were found in macrophages located near activated T cells, and were associated with improved or impaired stroke outcome, depending on the relative predominance of neuronal or myelin epitopes, respectively [212]. The reasons for the discrepant effects of neuronal or myelin epitopes have not been elucidated and deserve further study. Other studies showed that immunization with myelin antigens worsened outcome in experimental models of cerebral ischaemia, and that systemic inflammation at stroke outset, or early in the disease course, primed autoreactive immune responses to CNS antigens such as myelin basic protein (MBP) and glial fibrillary acidic protein [213-215].

Collectively, these studies highlight the occurrence of self-reactive responses after acute brain ischaemia, although they do not clarify whether antigen-specific activation of immune cells is beneficial or detrimental, or how these effects are influenced by infections that precede or follow acute stroke. The mechanisms that govern protective versus non-protective T-cell responses specific to CNS antigens after stroke could depend on the anatomy of brain damage (that is, grey matter versus white matter damage), effector T-cell phenotype, activation of regulatory T (TREG) cells, genetic background, and/or other factors that determine the strength and timing of autoreactive T-cell activation.

A better understanding of the mechanisms underlying autoreactivity after acute stroke could inform the development of new therapeutic strategies in the near future. Recombinant T-cell-receptor ligands comprising partial major histocompatibility complex class II (MHC-II) molecules have been developed that may act as partial T-cell-receptor agonists and direct autoreactive T cells to become nonpathogenic. For example, RTL551—which contains the myelin oligodendrocyte glycoprotein (MOG)-35-55 antigenic peptide—was successfully used as a neuroantigen-specific immunomodulatory treatment in a model of cerebral ischaemia, suggesting therapeutic potential in human stroke [216].

Cytoprotective Effects

T cells that are specific to myelin antigens can reduce secondary neurodegeneration, enhance neurogenesis and promote recovery after CNS injury, indicating that autoimmune responses might be protective under experimental conditions. Lymphocytes that had been tolerized to specific CNS antigens provided long-lasting local immunosuppression, leading to immunological tolerance on restimulation. For example, induction of immunological tolerance by intranasal or oral application of MBP or MOG weeks before stroke onset reduced infarct size and improved recovery in rodent stroke models. Intranasal administration of MBP also increased the frequency of Treg cells, and reduced the extent of TH1 responses to MBP. In addition, nasal instillation of E-selectin, which is specifically expressed on activated endothelium, was cytoprotective and prevented ischaemic and haemorrhagic strokes in rats. Overall, these findings could indicate that in patients with a history of stroke, antigen-specific immunomodulation might prevent recurrent stroke and improve stroke outcome, although recent studies have raised concerns about the potential to induce deleterious autoimmunity through mucosal administration of CNS antigens [217-223].

Regulatory T Cells

Numerous studies in animal models have shed light on the role of endogenous Treg cells in cerebral ischaemia. These cells are characterized by expression of the transcription factor forkhead box protein P3 (FOXP3) and are important regulators of immune homeostasis, both in health and immune-mediated diseases [224]. Treg cells can exert their anti-inflammatory effects by a direct interaction with various other cells, as well as by secretion of the cytokines IL-10 and transforming growth factor- β (TGF- β).

Interestingly, after extensive brain ischaemia, Treg cells are less susceptible to undergoing apoptotic cell death than are other splenocytes, suggesting a brain damage-related shift towards an anti-inflammatory phenotype in the adaptive immune system [225]. Indeed, endogenous Treg cells have an important protective role in ischaemia, as depletion of these cells in mice considerably increased infarct size and behavioural deficits after brain ischaemia.⁵⁷ These effects did not become evident until 3–7 days after middle cerebral artery (MCA) occlusion. Moreover, depletion of Treg cells exacerbated damage in models of moderate cortical or subcortical ischaemia, but not in models of extensive ischaemia—a finding that has been reproduced using another paradigm [226]. In contrast to the late migration of Treg cells into the CNS and the delayed effect of these cells on tissue damage, Treg-cell depletion has profound effects on early activation of and cytokine production by brain microglia. Moreover, depletion of Treg cells enhances activation of invading proinflammatory T cells, eliciting increased expression of the inflammatory cytokine IFN- γ . The protective effect of Treg cells in animal models is mediated by IL-10, which is consistent with the beneficial effects of therapeutic IL-10 delivery to the brain [227].

B Cells

Regulatory B cells were recently reported to have beneficial effects on the ischaemic brain as early as 24–48 h after MCA occlusion.⁽⁸⁷⁾ Lack of B cells substantially increased infiltration of various leukocyte subpopulations into the brain, and reduced their functional activation. Conversely, transfer of B cells into the brain reduced infarct size and production of inflammatory cytokines by peripheral T cells [228].

An Integrated Immune Response

Brain ischaemia results in oxidative stress, complement activation, and blood clotting (Figure 5). These mechanisms contribute to vascular damage and lead to infiltration of the brain parenchyma by immune cells according to a temporal pattern that is coordinated by upregulation of chemoattractant and adhesion molecules. Neutrophils release proteases that can further damage BBB integrity and exacerbate oxidative stress [229]. The early clinical course of stroke is influenced by circulating monocytes and macrophages—cells that also participate in clearance of debris and damaged cells at later stages, which represents an important step before regenerative processes can be initiated. Dendritic cells and lymphocytes accumulate in the ischaemic brain parenchyma early after stroke onset, although their contribution to immune regulation in post-ischaemic inflammation remains to be fully elucidated. Glial cells develop an inflammatory phenotype in response to ischaemia, and release mediators that attract neutrophils, monocytes and lymphocytes. DAMPs that are

released by necrotic cells contribute to amplification of the innate immune response and activation of T cells [230].

The adaptive immune system is activated by acute stroke, as cell death results in release of brain antigens to the extracellular milieu. These antigens can subsequently reach the cervical lymph nodes and palatine tonsils by passing through the cribriform plate and travelling along basement membranes in the walls of capillaries and cerebral arteries. Some reactive forms of microglia, infiltrating macrophages and dendritic cells express MHC-II receptors and can, therefore, present brain antigens to T cells and B cells in lymphoid tissue. These cells can also provide the cytokine stimulus for T-cell activation [230].

In animal models, the presence of brain antigens in the cervical lymph nodes is sufficient to stimulate a T-cell-mediated reaction [231]. Antigen-specific T lymphocytes probably circulate from nodes in other parts of the body to cervical lymph nodes, where they receive an 'address' to target the brain through the expression of integrins on their surface, thereby enabling them to specifically target the injured cerebral hemispheres. B-cell activation leads to generation of antibodies against specific brain-derived molecules, whereas T-cell activation might be involved in autoimmune or tolerance reactions. The interplay of various cytokines influences adaptive responses. Anti-inflammatory molecules, such as IL-10 and TGF- β , and regulatory cells, such as T_{reg} and B-regulatory cells, can have a prominent beneficial role, probably by dampening proinflammatory and self-directed reactions to the brain tissue. Serum IL-10 levels have been suggested as a marker of stroke severity and outcome in patients. However, the effects of therapeutic IL-10 delivery have not yet been examined in patients [232].

Stroke-Induced Immunodepression

Acute stroke can cause a stroke-induced immunodepression (SIID) syndrome. The proportion of patients with stroke who develop SIID is unknown, as a commonly accepted definition of SIID and representative investigations in large stroke populations are lacking. The rate of SIID can, however, be estimated as 30% according to the frequency of poststroke infections. Manifestations of systemic immunodepression are not unique to stroke or to other acute injuries to the CNS, as they can also occur after traumatic injury, severe burns or brain surgery. These conditions all seem to be accompanied by a large outflow from the autonomic nervous system that profoundly affects the innate and adaptive immune response and is responsible, at least in part, for the increased susceptibility to subsequent bacterial infections (Figure 7) [233-234].

CNS injury can also directly induce immunodepression. This unique feature of acute brain damage might cause a different systemic immune response to that induced by severe body trauma without CNS injury, and is a matter of intense research [233]. The role of hepatic invariant natural killer T (iNKT) cells in mice and the release of acetylcholine by splenic memory T cells in SIID (Figure 6) were recently highlighted. iNKT cells have a highly restricted repertoire of T-cell receptors that recognize lipid antigens presented by CD1. After experimental stroke in mice, iNKT cells showed a noradrenergic-mediated anti-inflammatory phenotype that increased susceptibility to infections. The anti-inflammatory

phenotype was reversed with administration of the β -blocker propranolol or the immunomodulator α -galactosylceramide [235-237].

Teleologically, SIID could represent an adaptive response to limit ischaemia-induced inflammation in the brain, although it can facilitate the emergence of infections owing to reduced inflammatory drive [237]. Lymphocytopenia is a consistent hallmark of SIID, but conflicting evidence exists regarding the functional status of the surviving T lymphocytes. Specifically, previous studies found that proinflammatory T cells from patients with SIID responded less strongly to *in vitro* stimulation than did such cells from healthy controls [238], but recent studies have shown that both effector and Treg cell subpopulations sustain their proliferative capacity after stroke in mouse models and in humans [239-240].

Figure 7. The anti-inflammatory reflex and poststroke infection.

The CNS modulates the activity of the immune system through complex humoral and neural pathways that include the hypothalamic–pituitary–adrenal axis, the vagus nerve and the sympathetic nervous system. The hypothalamus is functionally linked with autonomic centres, allowing the synchronization of neuroendocrine (glucocorticoid) responses with the cholinergic pathway, which together suppress the peripheral release of inflammatory cytokines from T cells, monocytes and macrophages, and promote the release of anti-inflammatory cytokines such as IL-10. Similarly, release of noradrenaline from a dense network of neurons throughout the brain and from peripheral organs, including the adrenal medulla, the liver and the spleen, induces a pronounced anti-inflammatory phenotype in lymphocytes, monocytes and macrophages. Together, these mechanisms limit the inflammatory response in the brain but can facilitate the emergence of infections such as pneumonia and urinary tract infections. Release of catecholamines from nerve terminals may induce profound behavioural changes in hepatic iNKT cells, and release of acetylcholine by splenic memory T cells, both of which could prevent inflammation and promote the emergence of infection after stroke. Abbreviations: iNKT, invariant natural killer T; TNF, tumour necrosis factor.

A crucial component of SIID in patients with stroke and in experimental conditions [241-242] is overactivation of the adrenergic system, which acts on peripheral immune cells to cause a switch from a proinflammatory TH1 response to an anti-inflammatory TH2 response. Sympathetic activation can also result in gastrointestinal dysmotility [243], which increases the risk of developing aspiration pneumonia.

Neuroprotection by Antibiotics

Antibiotics can be used after acute stroke to prevent infection, but could also offer neuroprotection. Minocycline does not cover the full spectrum of bacteria that commonly cause pneumonia and urinary tract infections, but is used to treat patients with acute stroke owing to its neuroprotective properties. Minocycline has anti-inflammatory effects and improves outcome in experimental stroke studies, although these effects were not reproduced in a recent preclinical drug evaluation [244-248].

β -Lactams are another class of antibiotics with reported neuroprotective properties. In this case, neuroprotection is mediated by increased glutamate transporter expression. In a neonatal rat model of cerebral ischaemia, pretreatment with ceftriaxone significantly reduced brain injury and hippocampal cell apoptosis, restored myelination in the external capsule, and increased expression of the glutamate transporter GLT1 in cortical neurons [244]. GLT1 is mostly expressed in mature astrocytes and is the main glutamate transporter in the brain. Excessive glutamate release induced by cerebral ischaemia can cause neuronal damage, and increased glutamate transporter activity could, therefore, explain the putative neuroprotective effects of ceftriaxone. Ceftriaxone has a broad spectrum of activity against bacteria that cause infection after acute stroke. The combined properties of ceftriaxone, therefore, suggest that this drug could prevent infection after acute stroke as well as limiting neuronal damage, although its effects on functional outcome in patients with stroke remain unknown [244].

ROLE OF T CELLS IN ISCHEMIC STROKE

Following an ischemic stroke, T lymphocytes become activated, infiltrate the brain, and appear to release cytokines and reactive oxygen species to contribute to early inflammation and brain injury. However, some subsets of T lymphocytes may be beneficial even in the early stages after a stroke, and recent evidence suggests that T lymphocytes can also contribute to the repair and regeneration of the brain at later stages. In the hours to days after stroke, T-lymphocyte numbers are then reduced in the blood and in secondary lymphoid organs as part of a 'stroke-induced immunodeficiency syndrome,' which is mediated by hyperactivity of the sympathetic nervous system and the hypothalamic-pituitary-adrenal axis, resulting in increased risk of infectious complications. Whether or not poststroke T-lymphocyte activation occurs via an antigenin dependent process, as opposed to a classical antigen-dependent process, is still controversial. Although considerable recent progress has been made, a better understanding of the roles of the different T-lymphocyte subpopulations and their temporal profile of damage versus repair will help to clarify whether T-lymphocyte targeting may be a viable poststroke therapy for clinical use.

T lymphocytes are central to the development of a sustained inflammatory response and there is now good evidence that these cells accumulate in the postischemic brain within a few hours of reperfusion [249]. Here in this section of the chapter we will briefly summarize the emerging evidence of complex roles of T cells in brain injury after stroke. As shall be discussed, T cells are sources of pro-inflammatory cytokines and cytotoxic substances, such as reactive oxygen species, in the brain after stroke, which likely contribute to neuronal death and poor outcomes. However, future therapeutic efforts to treat stroke by targeting T cells must take into account the crucial roles that T cells have in host defense against invading pathogens, which appears to be critically important in the period following a stroke. Furthermore, recent evidence for a novel role of T cells in promoting brain tissue repair and regeneration in the weeks and months after stroke will also be discussed in this section.

T-Lymphocyte Subtypes and Characteristics

T lymphocytes are bone marrow-derived leukocytes that mature in the thymus and have an integral role in the adaptive immune system (i.e., the division of the immune system that recognizes specific pathogens and can generate immune memory). As such, they are vital for clearing pathogens that cannot be cleared by the innate immune system alone (i.e., the division of the immune system that initially defends the body from infection, in a nonspecific manner) [250]. Several T-cell subtypes exist, and these can be differentiated by their unique expression profiles of specific coreceptor proteins. CD3 is expressed on the surface of 95% of the T cells that have exited the thymus and which are immunocompetent. The CD3⁺ subset comprises both CD4⁺ (or T-helper cells; TH) and CD8⁺ (or cytotoxic T cells; TC) cells in approximately equal proportions [250] (Figure 8).

TH cells do not kill cells directly, but instead help to activate other immune cells including TC cells, and can be further differentiated into three major types defined by the cytokines they secrete. Thus, TH cells can promote either: cell-mediated or inflammatory immunity (i.e., TH1 cells); humoral and allergic responses (i.e., TH2 cells) [251-252]; or inflammatory immunity to clear pathogens distinct from those handled by TH1 or TH2 cells, including fungi (i.e., TH17 cells) [253]. On activation, TH1 cells secrete proinflammatory cytokines such as IFN- γ (interferon- γ), TNF (tumor necrosis factor), and LT- α (lymphotoxin), whereas TH2 cells produce antiinflammatory cytokines such as interleukin-4 (IL-4) and IL-10. TH2 cells are thought to suppress pro-inflammatory immune responses, and commonly appear later in an immune response [251]. TH17 cells secrete IL-17, IL-21, and IL-22 [252]. An important CD4⁺ T-cell subtype that accounts for 10% of all CD4⁺ T cells [254] and which expresses CD25 and the transcription factor Foxp3, is the regulatory T cell (Treg; i.e., CD4⁺ CD25⁺Foxp3⁺ cells). Treg cells act to limit the immune response and thus prevent autoimmune disorders [255] via their release of transforming growth factor- β and IL-10 [202].

As their name suggests, the cytotoxic TC cells can directly kill cells that contain intracellular pathogens, such as viruses, through the release of the cytotoxins, perforin, and various granzymes (resulting in necrosis), or by the Fas-FasL pathway (resulting in apoptosis) [256]. TC cells also produce pro-inflammatory cytokines, such as IFN- γ and TNF, which serve to block viral replication as well as to promote the activation of other elements of the immune system [257]. Finally, 'unconventional' T lymphocytes that act to link the innate and

adaptive immune systems (and are often called innate-like lymphocytes) include gd T cells (B5% of T cells; the only T cells that do not express CD3) and natural killer T (NKT) cells [258].

Figure 8. Potential actions of T lymphocytes in the brain following stroke.

Following cerebral ischemia and reperfusion, circulating T lymphocytes interact with neutrophils, macrophages, platelets, and endothelial cells (ECs), and may cross the blood–brain barrier (BBB) to infiltrate the injured tissue. The two broad subpopulations of mature circulating T lymphocytes are T-helper cells (i.e., CD4⁺) and cytotoxic T cells (i.e., CD8⁺). It appears that both subpopulations contribute significantly to acute poststroke brain injury via several mechanisms. The small subpopulation of CD4⁺ regulatory T cells (i.e., Tregs) may act to limit some of these damaging effects by other T cells. In addition, CD4⁺ T cells, perhaps especially Tregs, may contribute to later repair processes, such as neurogenesis, during brain recovery (adapted from VH Brait et al., 2012 npg).

Recent studies of the postischemic brain microcirculation have revealed that the accumulation of T cells in postcapillary venules is generally accompanied by the recruitment of adherent platelets, suggesting that the venules assume both a proinflammatory and prothrombogenic phenotype after ischemic stroke [259]. The net impact of the accumulated platelets in the postischemic microcirculation remains unclear; however, inhibition of platelet tethering and adhesion to vascular endothelial cells (the early phases of platelet activation) has produced reductions in cerebral infarct volume [17, 260–261]. Furthermore, inhibition of early platelet adhesion and activation maintains cerebral blood flow during reperfusion [262]. A novel concept of ‘thrombo-inflammation’ suggests that there is a strong link between pathways of thrombus formation and inflammation, and recent evidence suggests that specific early platelet adhesion/activation mechanisms may in fact link these pathways to exacerbate infarct development following cerebral I–R [263]. However, it is currently unclear as to whether specific interactions between T lymphocytes and platelets have an important role in stroke outcome, as T-cell deficiency is reported to have no effect on thrombus formation [264].

POTENTIAL MEDIATORS OF DAMAGE BY T LYMPHOCYTES AFTER STROKE

Cytokines, Chemokines, and Cytotoxins

The mechanisms of T-cell-mediated brain injury following stroke are currently unclear. Classically, T cells kill bacteria- and virus-infected cells either via the release of cytokines (in the case of TH and TC cells) or cytotoxins (also by TC cells) [250], and so it is plausible that similar actions may exacerbate poststroke brain inflammation. Cytokines and chemokines released by TH and TC cells are likely to increase expression of vascular adhesion molecules and attract other immune cells into the brain, resulting in widespread apoptosis [265]. Alternatively, TC cells may directly cause either cell necrosis or apoptosis via the release of cytotoxins or the activation of the Fas receptor [256]. Neutralization of certain T-cell-derived cytokines (e.g., IL-17, IL-12, IL-23) was found to reduce infarct volume and improve neurologic outcome scores over 7 days poststroke [51, 206], consistent with these T-cell-derived cytokines contributing to brain injury early after I-R. Furthermore, Liesz et al., (2009b) showed that CD3⁺ T cells are a major source of the damaging pro-inflammatory cytokine, IFN- γ , in the ischemic hemisphere. When neutralizing antibodies against IFN- γ were administered into the cerebral ventricles, there was a significant reduction in infarct volume [203]. Consistent with these results was the finding that reduced mRNA expression of various proinflammatory cytokines, chemokines, and chemokine receptors (TNF- α , IL-6, IL-10, IP-10, CCR1, CCR2, CCR3, and CCR5) occurs after stroke in the brains of SCID mice compared with wild-type mice [49]. Taken together, current evidence suggests that T cells (potentially excluding the immunomodulatory subset of Treg cells) represent a major source or stimulus of pro-inflammatory cytokines in the brain following stroke. Moreover, stroke in perforin-deficient mice produce a significantly smaller infarct volume, suggesting that the cytotoxin perforin, released by TC cells, contributes to ischemic damage [209].

Reactive Oxygen Species

There is recent evidence that T lymphocytes may contribute to oxidative tissue injury following stroke, potentially via the release of NADPH oxidase type 2 (Nox2)-derived superoxide. First, it is quite clear that oxidative stress due to excessive levels of reactive oxygen species is a major mechanism of poststroke brain injury. Studies of stroke in mice either overexpressing antioxidants or deficient in pro-oxidant enzymes have reported smaller infarct volumes than in wild-type controls [266-268], and conversely, studies of antioxidant-deficient mice have found larger infarcts [269-270]. Moreover, several studies in Nox2-deficient mice have reported substantially smaller infarct and edema volumes, and less blood-brain barrier disruption than wild-type controls, pointing to Nox2 oxidase as a key source of damaging superoxide in the brain after stroke [271-273]. T lymphocytes are now known to contain a functional Nox2 oxidase and, at 24 hours following stroke, circulating T cells produce B7-fold greater amounts of Nox2-derived superoxide than do T cells from control mice. Interestingly, much greater levels of superoxide are generated by circulating T cells compared with spleen-derived T cells after stroke [249, 274], consistent with the possibility

that exposure to the circulation (and/or postischemic brain tissue) upregulates Nox2 oxidase activity in T lymphocytes. In addition to Nox2, a recent study by Kleinschnitz et al., [50] has identified NADPH oxidase type 4 (Nox4) as an important source of oxidative stress and an effective therapeutic target in acute stroke. Nox4 was induced in human and mouse brain following ischemic stroke, and mice deficient in Nox4 (Nox4^{-/-}) developed smaller infarct volumes, had improved functional outcomes, and were largely protected from oxidative stress, blood–brain barrier leakage, and neuronal apoptosis, after both I–R and permanent cerebral ischemia.

Mechanism(s) of T-Lymphocyte Activation after Stroke

There is currently a major unanswered and controversial question regarding the mechanism(s) of T-lymphocyte activation following stroke. Based on the information gained from decades of study in the area of immunology, it is apparent that the activation and infiltration of T cells into the brain following stroke is too quick for it to occur via a classical antigen-dependent response (Offner et al, 2006a). Traditionally, it has been believed that for T cells to infiltrate into tissues, cellular activation leading to a change in the expression of surface molecules (e.g., VLA-4, CCR5, and CD44) is required [250,275]. Classical antigen-dependent activation of naive T cells comprises two main steps and takes 7 to 10 days [276]. The first step involves the binding of the T-cell receptor (TCR) to the antigen presented on the major histocompatibility complex on the surface of an APC (antigen-presenting cell). The second step involves the binding of costimulatory molecules on the T cell and the APC, such as CD28 on the T cell and CD80 (B7.1) and CD86 (B7.2) on the APC [277]. An elegant recent study by Kleinschnitz et al., in 2010 indeed found evidence that the antigen-dependent activation of T cells is not required for them to contribute substantially to the infarct volume present at 24 hours after cerebral I–R. Through the use of various transgenic mice, including Rag1^{-/-} mice reconstituted with CD3⁺ T cells, TCR-transgenic mice (bearing a single CD4⁺ or CD8⁺ TCR) or mice lacking costimulatory molecules, it was found that neither the first signal (antigen recognition) nor the second signal (costimulation) of classical T-cell activation was required for the T-cell-dependent damage to occur after stroke [264].

That is not to say that previously activated T lymphocytes, for example, due to preexisting infection or even cardiovascular disease [278], could not cause additional damage in the brain following I–R. The mechanism(s) of this antigen-independent T-cell ‘activation’ within hours after stroke are currently unknown. On the other hand, antibodies to neuroantigens reportedly increase following stroke, as do myelin basic protein reactive T cells [210–211]. Furthermore, another two studies reported that administration of the recombinant TCR ligand, RTL551 (which blocks classical antigen-dependent T-cell activation) linked to a CNS antigen, resulted in a reduced infarct volume following cerebral I–R [279].

Because this protective effect only occurred when RTL551 was linked to a neuroantigen, rather than a nonneuronantigen [57], it suggests that an adaptive immune response to brain antigens occurred following stroke, and that classical T-cell activation may indeed have contributed to postischemic brain damage. Moreover, tolerance against brain antigens by mucosal administration of the antigen before stroke has been reported to improve outcome after stroke [52, 56, 220], further suggesting that antigen-dependent lymphocyte activation occurs following stroke, and that it contributes to brain injury. Therefore, the contribution of

antigen-dependent T-cell activation in the damaging effects of T cells acutely poststroke remains unclear.

T-Lymphocyte-Targeted Experimental Therapies Anti- α 4 Integrin Antibody

Several studies have sought to prevent T-cell infiltration into the brain after stroke, for example, by targeting the α 4 integrin with neutralizing antibodies [280-281]. α 4 Integrin is part of the VLA-4 protein that is expressed on > 70% of all leukocyte populations, including T cells [209], and which binds to VCAM-1 expressed on endothelial cells. Vascular cell adhesion molecule-1 mRNA and protein [209, 229] are reported to be strongly induced in the microvasculature of the ischemic area following cerebral ischemia, and this expression is important for T-cell infiltration into the brain [282-83].

Furthermore, another study that treated mice with a monoclonal antibody against the α 4 integrin reported a reduced infarct volume at 7 days after a 30-minute I-R or permanent cerebral ischemia, as well as an improved sensorimotor activity 3 and 7 days after permanent ischemia [42]. This protection was confirmed to occur via limiting the effects of lymphocytes, as α 4 integrin blockade had no effect in Rag2^{-/-} mice. In addition, in both TH and TC cell-depleted mice, α 4 integrin blockade had no further effect on infarct volume, providing good evidence that the efficacy of α 4 integrin blockade is mediated by targeting T cells [203]. Interestingly, at 5 days after cerebral ischemia, the brain infiltration of all T-cell subsets examined (including TH, TC, Treg, and NKT cells) was significantly reduced, as were the infiltration of B cells and granulocytes. Together, these findings might suggest that even though multiple leukocyte types enter brain lesions after transient I-R, much of the (at least α 4 integrin inhibitable) damage is mediated by T cells.

Anti-Vascular Cell Adhesion Molecule-1 Strategies

The means by which VCAM-1 is targeted appears to be critical in the outcome achieved by anti-VCAM-1 therapy after stroke. Intravenous or intraperitoneal administration of anti-VCAM-1 antibodies have been unsuccessful at protecting against ischemic brain damage either in rats or in mice. While VCAM-1 blockade reduced the number of monocytes/macrophages/reactive microglia present in the ischemic rat brain, it did not reduce the numbers of infiltrating neutrophils and lymphocytes [284, 203]. In contrast, when utilizing hydrodynamic *in vivo* administration of VCAM-1 small interfering RNA, granulocyte and T-cell infiltration into the brain was reduced in association with a reduced infarct volume at 6 days after stroke. Moreover, after this *in vivo* silencing of VCAM-1, anti- α 4 integrin antibody administration produced no further reduction of infarct volume suggesting that VCAM-1 is the main endothelial receptor for VLA-4 on infiltrating T lymphocytes [203]. Interestingly, a very recent study found that a high plasma level of ALCAM in patients with acute ischemic stroke was predictive of a poor prognosis, raising the possibility that anti-ALCAM strategies might be considered clinically for acute stroke therapy [285].

FTY720

Another widely tested therapeutic in experimental stroke is the immunosuppressant FTY720, a stable analog of the lipid signaling mediator sphingosine 1- phosphate. Many experimental stroke studies have found reductions in infarct volume, and improvements in functional outcome [207-208, 286] following administration of FTY720, a drug known to sequester lymphocytes in lymph nodes, preventing them from moving to the CNS for autoimmune responses in multiple sclerosis. One study even found improvements in functional outcome up to 15 days after cerebral ischemia [208]. Shichita et al., (2009) found FTY720 to inhibit T-cell infiltration into the infarcted zone, and others have reported fewer infiltrating neutrophils and activated microglia/ macrophages in the ischemic lesion [51, 286-287].

Furthermore, FTY720 was found to reduce apoptotic cell death in the ischemic hemisphere as well as the expression of intercellular adhesion molecule-1-positive blood vessels in the brain. However, a recent study could not detect any reduction of infarct volume or behavioral dysfunction following permanent cerebral artery occlusion despite a reduced lymphocyte brain invasion after FTY720 treatment [203, 208]. This lack of neuroprotection despite effective lymphopenia was suggested to be due to a divergent impact of FTY720 on cytokine expression and possible activation of innate immune cells after brain ischemia [203].

FK506 and Cyclosporin A

Other immunosuppressive drugs, such as FK506 (Tacrolimus) and CsA (Cyclosporin A), have also been tested in experimental stroke studies. The immunosuppressive actions of FK506 and CsA involve the inactivation of NFAT (nuclear factor of activated T cells) via the inhibition of calcineurin. FK506 was first shown by Sharkey and Butcher (1994) to be a powerful neuroprotective agent in an in vivo model of focal cerebral ischemia when administered up to 60 minutes after occlusion. The minimum effective neuroprotective doses of FK506 and CsA are comparable with the immunosuppressant doses in humans, however, suggesting that a broad immunosuppressive effect predisposing to infection may complicate the clinical use of these drugs as a treatment for stroke [288-292].

RTL551

As mentioned above, two recent studies reported that postischemic administration of a recombinant TCR ligand (RTL551, which acts as a partial agonist at the TCR and blocks T-cell activation) linked to a CNS antigen, reduced cerebral infarct volume by up to 33% at 96 hours. These protective effects were associated with less brain infiltration by T cells, B cells, NK cells, and macrophages/microglia, and especially dendritic cells and activated microglia/macrophages [57], as well as fewer activated TH (CD44⁺CD4⁺) cells in the circulation [279].

Chemokine Receptor Antagonists

Chemokine receptors could be attractive novel targets for modulating T-cell-mediated damage poststroke. Chemokine receptors are expressed on leukocytes and, by binding with a high degree of specificity to chemokines released from damaged tissues, they promote the migration of leukocytes to sites of injury [293-294]. Several chemokines are upregulated in the brain following cerebral I-R in mice, underpinning the attraction of different leukocyte subtypes into the brain. We have provided proof-of concept that inhibition of chemokine/chemokine receptor interactions with a small molecule chemokine receptor antagonist (SB225002, a CXCR2 antagonist) can modulate the leukocyte profile in the brain following stroke [295]. We speculate that more detailed identification of the specific chemokine/chemokine receptor interactions that are involved in the attraction of damaging T-cell subsets (and any other leukocytes responsible for poststroke brain injury) may enable selective inhibition of their infiltration into the brain following stroke, without preventing the entry of those T-cell subsets that are involved in brain repair and regeneration (). Moreover, targeting T-lymphocyte migration into the brain following stroke (as opposed to targeting their activation) may have the added advantage of maintaining the levels of these cells in the periphery where they are needed to fight infections.

Evidence for T Lymphocyte Involvement in Brain Regenerative Processes after Stroke

Following the acute pathological events that occur in the hours to days after an ischemic stroke, regenerative processes associated with neurologic recovery take place in the brain, over several weeks or even months. During this process, the brain repairs and reorganizes in a manner similar to that which occurs during the early stages of development [296]. The creation of new neural networks through neurogenesis, neuroplasticity, synaptogenesis, angiogenesis, and gliogenesis helps to repair and reorganize the brain. Inflammation has been suggested to have a key role in the promotion of these reparative processes, mainly through the release of growth-related proteins and cytokines, potentially from T lymphocytes as well as other peripheral and resident immune cells. Neurogenesis occurs continually in the hippocampus throughout adult life [294], but when T cells are depleted, this neuronal cell proliferation is impaired, suggesting that T cells are required for neurogenesis [297-298]. This appears to be specifically due to the actions of CD4⁺ and not CD8⁺ T cells [297], and it occurs through classical CNS antigen-dependent T-cell activation [298] via the release of neurotrophic factors, such as nerve growth factor, brain-derived neurotrophic factor, and neurotrophin-3 [299]. Thus, CNS-specific CD4⁺ T cells could be involved in the promotion of neurogenesis after brain injury, such as in stroke, and antigen-activated T cells at the site of injury could have a role in the repair of damaged tissue. By contrast, a recent study by Saino et al., (2010) reported that CD4⁺ T cells in the brain might inhibit neurogenesis following stroke. In mice depleted of CD4⁺ (but not CD8⁺) T cells, there was a greater proliferation of neurons at 28 days after stroke. However, it is important to note that these studies were performed using a model of permanent ischemia, and it is possible that the effect of T cells is different if reperfusion does not occur. Interestingly, when Treg cells are selectively depleted, neurogenesis is also reduced [300], suggesting that Treg cells may be a key CD4⁺

subpopulation of T cells that is required for neurogenesis. Moreover, Treg cells are also reported to modulate postischemic neovascularization following femoral artery ligation [254], and so any similar action by Treg cells to promote cerebral neovascularization after stroke would represent a further important role by this subset of T cells in the recovery of brain function following ischemia.

Complications and limitations to be considered in targeting T lymphocytes as poststroke therapy With tPA (tissue plasminogen activator) still being the only therapy available for acute ischemic stroke patients, novel effective therapies that can be administered beyond 4.5 hours are desperately needed. As acute inflammation appears to occur in the brain for many hours or even days after ischemic stroke [301], targeting key circulating immune cells to prevent their activation and/or extravasation would, at face value, seem to be a rational approach. Although therapies that target T cells in this manner relatively soon after stroke may reduce brain injury and improve poststroke outcome, there are several potential complications and likely limitations to the usefulness of T-cell inhibition after stroke.

First, in the short term, as the profound systemic immunodepression that rather quickly follows ischemic stroke will already have substantially weakened the immune system and thus increased the risk of infection [86,89, 303], further pharmacological approaches that attenuate immune cell function beyond this point (possibly within only a few hours) may do more harm than good by exacerbating the immunodepression. It should be noted that infection is the most common cause of death in the postacute phases of stroke with 23% to 65% of all stroke patients acquiring infections within the first few days [304-305].

Second, in the longer term (i.e., days to weeks) as mentioned above, inflammation—including via effects of T cells—appears to eventually have a role in promoting brain regeneration in the postacute phase of an ischemic stroke. For example, neurogenesis is reported to begin 5 days after stroke, and thus any therapy that interfered with these processes would be contraindicated.

Third, it is unclear how important T cells are as contributors to acute brain injury after ischemic stroke in the absence of effective reperfusion (either spontaneous or tPA induced), which still represents the majority of clinical cases. If their role is minimal, then anti-T-cell therapy may only be appropriate to be given in combination with successful reperfusion by tPA.

Fourth, the possibility of blocking T-cell subtypes with important antiinflammatory actions (e.g., Treg cells or NKT cells) would also be a limitation to its efficacy. More research is therefore needed to clarify the plausibility of safely and effectively inhibiting T-cell-mediated brain injury in the early stages after stroke, and perhaps even at later times using mild pro-inflammatory treatments (including neurotrophic factors) to promote repair and regeneration [306-307]. Additionally, the recent work by Wong et al., (2011) has raised the possibility of using selective activators of NKT cells to prevent stroke-associated infections [235].

SUMMARY AND CONCLUSION

Immunity and inflammation are an integral part of the pathogenic processes triggered by I/R. Inflammatory signaling is responsible for early molecular events triggered by the arterial

occlusion and culminating in the invasion of the brain by blood-borne leukocytes. Although its ultimate goal is to reestablish homeostasis, inflammation inflicts considerable damage to the metastable penumbral tissue. Adaptive immunity is deeply involved in the central and peripheral events triggered by cerebral ischemia, but evidence that a classical autoimmune response against brain antigens unveiled by tissue damage contributes to the acute phase of the damage is lacking. Lymphocytes invade the ischemic brain and contribute to tissue damage, but the rapidity of their deleterious effect is not consistent with an adaptive immune response targeted to the brain. Remarkably, selected lymphocyte subpopulations are protective, acting to dampen the cytotoxic effects of other inflammatory cells and promoting tissue recovery. The mechanistic bases for this dichotomous response of lymphocytes remains to be elucidated (Figure 3). Although the participation of inflammation and immunity in tissue recovery is well established in other organs, very little is known about these processes in the brain. Even less clear are the long-term effects of the adaptive immune response associated with stroke, and their role in the sequelae of ischemic damage, such as brain atrophy and dementia. Similarly, it is unclear if the immune system develops a memory of the antigen exposure and if an autoimmune response develops following subsequent exposure to the same antigen, as it may occur in cases of recurrent strokes.

The realization that the immune system and inflammation are central to the pathophysiology of stroke has raised the prospect of new therapeutic approaches to counteract ischemic injury. However, our understanding of the crosstalk between the immune system and the ischemic brain is still rudimentary and, as suggested by failed clinical trials, not adequate to guide therapeutic interventions. Modulation of adaptive immunity may afford the opportunity to deviate the post-ischemic immune response away from tissue damage and towards protection, an approach very effective in stroke models. However, immune-modulation can also have deleterious effects that need to be considered. Nevertheless, the remarkable impact that modulation of the immune system has on stroke damage and repair, justifies the aggressive pursuit of basic and clinical investigations seeking to unravel the fundamental processes governing the interaction of the ischemic brain with the immune system.

Innate immune system, triggered immediately and kept for a while after ischemic stroke onset, protects and hurts brain by activation of endogenous and exogenous immune cells and production of cytokines. Immunomodulatory therapies targeting the poststroke inflammation are promising with great obstacles, and a comprehensive understanding of innate immune response to cerebral ischemic attack calls for further investigation.

The relationship between the CNS and the immune system is complex and remains incompletely understood. It has particular salience after stroke and other forms of CNS injury, which trigger immune processes that seem to be both beneficial and harmful. A major frontier in stroke research involves efforts to better understand these interactions to develop new strategies and drugs that will prevent and reduce the burden of stroke. Based on current knowledge, physicians should be mindful that underlying inflammation is a biomarker of stroke risk and should carefully consider antithrombotic, statin, and antihypertensive therapy in vulnerable populations. Further work will be needed to delineate precise clinical strategies for risk factor modification based on specific biomarkers. In addition, it would be reasonable to administer statin drugs to patients with acute stroke given data suggesting that this improves outcomes, possibly as a result of anti-inflammatory properties. Furthermore, physicians caring for patients with stroke should recognize that poststroke immunodepression

increases the risk of infection and should adjust their clinical suspicion and treatment strategies accordingly. Whether a strategy of routine prophylactic antibiotic administration after stroke is beneficial remains unknown, but it holds promise as a simple method for improving poststroke outcomes. Finally, the care of patients with stroke may be improved by advances in specific areas, including investigation of whether modulating inflammatory pathways can reduce the risk of stroke and decrease penumbral ischemia during acute stroke, whether immunity has a role in poststroke functional recovery and dementia, and whether strategies to prevent poststroke immunodepression can reduce the incidence of infection after stroke without increasing dangerous autoimmunity against the brain. The immune system has not traditionally been the subject of therapeutic manipulation in patients with stroke, but given its intertwined relationship with the CNS, it promises to be an exciting avenue for future attempts to reduce the high burden of disability and death from stroke.

The study of the immune system is receiving increasing attention in the field of stroke, and detailed knowledge of the complex interactions between the innate and adaptive immune systems should improve our understanding of the disease course and the increased risk of infections after stroke. Emerging data are confirming, both at the bench and at the bedside, the influence of neurohormonal factors and the autonomic nervous system on the risk of poststroke infection. Studies in animal models have highlighted the involvement of immune cells that are resident in peripheral organs, such as the liver, in modulating infection after stroke—a phenomenon that needs to be investigated in patients in future studies. Similarly, further studies are required to address the apparently heterogeneous clinical consequences of the immune system responses that are associated with different cellular compartments of the CNS. Clarification of the mechanisms that produce the benefits and harmful effects of different lymphocyte subpopulations will also be an essential step in developing immunomodulatory therapies for acute stroke. In summary, this Review emphasizes the double-edged nature of the crosstalk between the CNS and the immune system in acute stroke, and highlights the strong need for further translational research.

In the last 5 years or so, there have been substantial advances in our understanding of the pathogenic role of T lymphocytes in ischemic stroke. These cells, traditionally belonging to the adaptive immune system, are now established to contribute to the infarct volume in the postischemic brain. Current evidence suggests that following an ischemic stroke, a systemic immunodepression occurs, T lymphocytes enter the brain and release cytokines/chemokines and superoxide, and contribute substantially to neuronal injury. Importantly, some types of T cells may be beneficial (e.g., Treg cells and NKT cells), and T cells may also have a longer-term role in general regenerative processes that occur in the later stages following an ischemic stroke. T lymphocytes may produce their damaging acute effects following activation via a nonclassical, antigen-independent process but this point is still controversial. After 7 to 10 days, T lymphocytes may additionally become activated in the classical manner, producing neurotrophins and contributing to neurogenesis. In conclusion, the role of T lymphocytes in ischemic stroke is complex and remains poorly understood. More research is needed to gain a greater understanding of which T-cell subpopulations produce the most damage, how and when this occurs, and when T cells may cease causing damage and begin contributing to regeneration. With this information, it will become apparent whether therapeutic targeting of T lymphocytes is likely to offer benefits for stroke patients.

Chapter 18

NATURAL HERBS, HUMAN BRAIN AND NEUROPROTECTION

Manzoor A Mir^{1,*}

¹Department of Bioresources, Faculty of Biological Sciences,
University of Kashmir, Srinagar-190006, India

ABSTRACT

A considerable amount of research has been invested into the development of novel treatments capable of protecting the brain from damage following stroke, with limited success. In ischemic stroke, the primary focus of treatment is reperfusion. Currently, the only drug approved for the treatment of ischemic stroke is recombinant tissue plasminogen activator (rtPA, alteplase), which has a limited time window for administration and increases the risk for subsequent hemorrhage. Humans consume a wide range of foods, drugs, and dietary supplements (Phytochemicals) that are derived from plants and which modify the functioning of the central nervous system (CNS). This chapter assesses the current evidence for the efficacy of a range of readily available plant-based extracts and chemicals that may improve brain function and which have attracted sufficient research in this regard to reach a conclusion as to their potential effectiveness as nootropics. Many of these candidate phytochemicals/extracts can be grouped by the chemical nature of their potentially active secondary metabolite constituents into alkaloids (caffeine, nicotine), terpenes (ginkgo, ginseng, valerian, *Melissa officinalis*, sage), and phenolic compounds (curcumin, resveratrol, epigallocatechin-3-gallate, *Hypericum perforatum*, soy isoflavones). They are discussed in terms of how an increased understanding of the relationship between their ecological roles and CNS effects might further the field of natural, phytochemical drug discovery. Currently there are no approved treatments for the myriad of damaging pathological processes that persist in the brain long after the acute stage of ischemic injury. These include the processes of inflammation, excitotoxicity, oxidative stress, apoptosis, and edema resulting from disruption of the blood brain barrier. In hemorrhagic stroke, additional processes include physical damage from the mass of accumulated blood itself, cytotoxicity of blood

components, and vasospasm in subarachnoid hemorrhage. In spite of decades of focused research on stroke treatment options still remain limited. Numerous neuroprotective treatments have been identified that show great promise in animal models of stroke. Natural compounds with the effects of anti-oxidation, anti-inflammation, calcium antagonization, anti-apoptosis, and neurofunctional regulation exhibit preventive or therapeutic effects on experimental ischemic brain injury. The prevention of cerebrovascular diseases has been one of the primary goals of researchers but unfortunately, to date, no such safe preventive agents are available. There is an urgent need for agents that are pharmacologically safe, cost-effective, and immediately available with minimal side effects. Here in this chapter, we will discuss the promising targets of neuroprotection and the natural products from traditional medicinal herbs that exhibit protective effects on ischemic brain injury. Further, we will provide an overview of targets for neuroprotection in stroke and examples of current research on potential neuroprotective treatments.

INTRODUCTION

Cerebral ischemia, which is one of the leading causes of death and disability worldwide, has attracted more and more attention in the field of drug discovery. Stroke is often caused by transient or permanent reduction of cerebral blood flow initiated by thrombotic or thromboembolic arterial occlusions [1-2]. The primary focus of treatment in stroke is reperfusion. Currently, the only drug approved for the treatment of ischemic stroke is recombinant tissue plasminogen activator (rtPA, alteplase), which has a limited time window. Thrombolytic therapy designed to restore cerebral perfusion in a timely fashion is considered the main rational therapeutic strategy for ischemic brain injury [3]. However, reperfusion after thrombolytic therapy often leads to a series of cellular, biochemical and metabolic consequences of cerebral ischemia, including intracellular reactive oxygen species (ROS) generation, calcium overload, excitotoxic cell injury and inflammation, which ultimately lead to irreversible brain injury. Moreover rtPA increases the risk for subsequent hemorrhage. Consequently, only a small percentage of patients receive rtPA treatment [3]. While this treatment is effective in opening up occluded cerebral vessels in some patients and can lead to improved outcomes after ischemic stroke, there are currently no approved treatments for the myriad of damaging pathological processes that persist in the brain long after the acute stage. These include the processes of inflammation, excitotoxicity, oxidative stress, apoptosis, and edema resulting from disruption of the blood brain barrier. Many neuroprotective agents are designed to protect the brain from irreversible injury after ischemia-reperfusion or to retard the pathological process [4, 5].

Recent studies have shown that damage to neurons after ischemia/reperfusion may occur through oxidative stress, inflammation and/or mitochondrial impairment that may culminate in the activation of an apoptotic cell death. Therefore, great emphasis has been given for the development of antioxidant, anti-inflammatory and antiapoptotic agents as therapeutics for stroke. Numerous lines of evidence from *in vitro* and *in vivo* studies have shown that plant-derived nutraceuticals have potential as antistroke agents.

Currently, research studies have focused on the possible capacity of natural herbs and the compounds extracted from fruits, vegetables and beverages to prevent ischemia and other neurological diseases. Some beneficial phytochemicals, display protective abilities in various

animal models of stroke and neurological disorders. In fact, many effective components extracted from traditional herbs have been demonstrated to show neuroprotection against ischemic brain injury in experimental studies. According to the pharmacological mechanisms elucidated in numerous reports, we evaluated the natural products that possess protective effects on ischemic brain injury and characterized the promising targets for ischemic brain injury.

But, despite decades of research, treatment options remain limited. Therefore, more and more attention in the field of drug discovery has been focused on neuroprotection by natural compounds from traditional medicinal herbs. Cerebral ischemia is a complex pathological process involving a series of mechanisms, and a framework for the development of neuroprotectants from traditional herb medicine is a promising treatment for cerebral ischemia.

Herbs that affect the functioning of Human Brain and provide neuroprotection

Humans consume a wide range of foods, drugs, and dietary supplements that are derived from plants and which modify the functioning of the central nervous system (CNS). The psychoactive properties of these substances are attributable to the presence of plant secondary metabolites, chemicals that are not required for the immediate survival of the plant but which are synthesized to increase the fitness of the plant to survive by allowing it to interact with its environment, including pathogens and herbivorous and symbiotic insects. In many cases, the effects of these phytochemicals on the human CNS might be linked either to their ecological roles in the life of the plant or to molecular and biochemical similarities in the biology of plants and higher animals. This section of the chapter assesses the current evidence for the efficacy of a range of readily available plant-based extracts and chemicals that may improve brain function and which have attracted sufficient research in this regard to reach a conclusion as to their potential effectiveness. Many of these candidate phytochemicals/extracts can be grouped by the chemical nature of their potentially active secondary metabolite constituents into alkaloids (caffeine, nicotine), terpenes (ginkgo, ginseng, valerian, *Melissa officinalis*, sage), and phenolic compounds (curcumin, resveratrol, epigallocatechin-3-gallate, *Hypericum perforatum*, soy isoflavones).

A huge scientific literature focusing on psychoactive herbal extracts and their phytochemicals, encompassing hundreds of thousands of scientific papers, has emerged over recent decades. The vast majority of these papers describe *in vitro* investigations of the potential mechanisms of action of putatively psychoactive phytochemicals, whereas a much smaller proportion explores their effects *in vivo* in animals and only a tiny minority investigate their efficacy in humans.

A vast number of natural, plant-based extracts and chemicals are purported to have beneficial effects on human brain function. Zhang identified extracts and constituents from 85 individual medicinal plants that have demonstrated potential efficacy for treating psychiatric disorders on the basis of animal behavioral models alone [6]. However, few plant-based products have been assessed in methodologically adequate human trials. A simple literature search using the individual names of the few extracts and compounds reviewed below (excluding nicotine and caffeine) generates some 30,000 publications. The 3 single polyphenols [epigallocatechin-3-gallate (EGCG), curcumin, and resveratrol] alone contribute 15,000 of these papers, the vast majority of which have been published in the last 10 yrs. This represents a huge amount of research and naturally raises the question of the ultimate efficacy

of the interventions in question. The following comprises a brief outline of the evidence surrounding the handful of herbal extracts and phytochemical supplements that have garnered enough evidence of efficacy or have been subjected to adequate levels of research to allow any conclusion as to their efficacy in terms of improved brain function. The polyphenols are included on the basis of the enormous interest they are generating currently. The palette of secondary metabolites can be subdivided into a number of distinct groups on the basis of their chemical structure and synthetic pathways, and these groups can, in turn, be broadly differentiated in terms of the nature of their ecological roles and therefore their ultimate effects and comparative toxicity in the consuming animal. The extracts/phytochemicals are therefore grouped below by the chemical nature of their putative active components. In this regard, the largest and most prevalent of phytochemical groups are the alkaloids, terpenes, and phenolic compounds.

Figure 1. Natural Herbs (Spices) with potential against Cerebrovascular diseases.

Numerous lines of evidence indicate that chronic inflammation plays a major role in the development of various cerebrovascular diseases. Extensive research over the last 10 years has indicated that nutraceuticals derived from such spices as turmeric, red pepper, black pepper, licorice, clove, ginger, garlic, coriander, and cinnamon target inflammatory pathways, thereby may prevent cerebrovascular and neurodegenerative diseases. The prevention of cerebrovascular diseases has been one of the primary goals of researchers, but to make prevention feasible, two objectives must be accomplished: (a) individuals at high risk for the disease must be identified before the symptoms become evident, and (b) compounds that are safe and effective in either reducing or slowing the disease progression need to be developed. Unfortunately, to date, no such safe preventive agents are available. There is an urgent need for agents that are pharmacologically safe, cost-effective, and immediately available with minimal side effects. Natural herbs like spices are one such source that has been used in cooking to add flavor and color to the food. A spice is a dried seed, fruit, root, bark, or flower of a plant. The use of spices has shaped a large part of the world's history. For example, the ancient Egyptians pioneered maritime trade to fetch the incense of Arabia; Greco-Roman navigators found their way to India for pepper and ginger; Columbus sailed west for spices; Vasco de Gama sailed east for them; and Magellan sailed across the Pacific Ocean on the same quest. Despite globalization, persons in Asian countries are still the largest consumers of spices. In ancient times, many spices were used as medicines for treating several diseases such as rheumatism, body ache, intestinal worms, diarrhea, intermittent fevers, hepatic diseases, urinary discharges, dyspepsia, inflammation, constipation, and dental diseases [7–8].

Figure 2. Chemical structure of common nutraceuticals derived from natural herbs (spices).

What was in such spices and how they exerted these activities remained obscure for ancient peoples. Modern molecular tools have shown that spices have active components, called nutraceuticals that contribute to the plethora of properties. Extensive research over the years has also identified the molecular targets of most nutraceuticals [9-10]. During the past decade, a number of nutraceuticals have been identified from spices (Figure 1). These nutraceuticals are chemically diverse (Figure 2) with a plethora of effects [11].

TARGETS FOR NEUROPROTECTION IN STROKE

Natural compounds with the effects of anti-oxidation, anti-inflammation, calcium antagonization, anti-apoptosis, and neurofunctional regulation exhibit preventive or therapeutic effects on experimental ischemic brain injury. Here in this chapter we will discuss the promising targets of neuroprotection and the natural products from traditional medicinal herbs that exhibit protective effects on ischemic brain injury. Further we will provide an overview of targets for neuroprotection in stroke and examples of current research on potential neuroprotective treatments.

Oxidative Stress as a Target for Neuroprotection in Stroke

The production of reactive oxygen species (ROS) and other free radicals during stroke is a consequence of excitotoxicity and the inhibition of cellular respiration in a low oxygen environment in addition to inflammation [12]. These molecules, such as hydroxyl radical, superoxide, and peroxynitrite, are highly reactive and damaging to multiple cellular components, leading to cell death (Figure 3). One way of reducing oxidative stress is to reduce the production of free radicals. Although nitric oxide is a normal signaling molecule in the body and has beneficial effects in stroke, larger amounts resulting from increased activity of the induced nitric oxide synthase (iNOS) can lead to aberrant signaling and or react with superoxide to produce peroxynitrite. Nebivolol decreases the expression of iNOS following bilateral CCAO in rats and increases expression of the beneficial endothelial nitric oxide synthase (eNOS), leading to a reduction in histopathological changes [13]. Another source of ROS is the nicotinamide adenine dinucleotide phosphate (NADPH) oxidases, and inhibitors of these enzymes could be beneficial in stroke [14]. Another method of protection is to induce endogenous mechanisms for the removal of free radicals in the body. Hydrogen sulfide gas increases the activity of superoxide dismutase and glutathione peroxidase in rats subjected to focal cerebral ischemia, resulting in decreased injury to neuronal mitochondria and a subsequent reduction in markers of apoptosis [15]. Hydrogen-rich saline increases endogenous antioxidant enzyme activity and decreases the amount of oxidative products in pMCAO rats [16]. A nucleic acid-based product improves the antioxidant status of neuronal mitochondria after transient ischemia in rats [17]. Alternatively, exogenous compounds with free radical scavenging properties can be used. The novel compound MnTm4PyP mimics the activity of endogenous manganese superoxide dismutase, and reduces infarct volume and neurological deficit after MCAO in mice [18]. An extract of *Ocimum sanctum* protects tMCAO rats by preserving reduced glutathione content and antioxidant enzyme activity [19]. Hydrogen gas

has been shown to neutralize free radicals and has beneficial effects on several contributors to early brain injury after subarachnoid hemorrhage in rats [20]. Furthermore, non-effective doses of the free radical scavenger lipoic acid enhance the neuroprotective effects of the NADPH oxidase inhibitor apocynin when given in combination to tMCAO rats [21]. Inhibition of downstream signaling pathways leading to oxidative stress induced damage, rather than the direct removal of ROS, may also have beneficial effects. The antioxidant N-tertbutyl- α -phenylnitron suppresses expression of complement component 3, a mediator of inflammation that is induced by oxidative stress, in mice after transient focal cerebral ischemia [22].

Natural Compounds with Anti-Oxidative Properties

Reactive oxygen species (ROS) is produced during ischemia/reperfusion, leads to the oxidation of lipids, proteins and DNA and subsequently cellular damage and apoptosis has now been well established [23-24]. Therefore, much attention has been paid to the rescue of brain injury after ischemia/ reperfusion via inhibition of ROS bursts. In fact, many natural compounds with antioxidant ability, such as flavonoids from *Scutellaria baicalensis* Georgi[25], Carnosic acid (CA), found in the herb rosemary obtained from *Rosmarinus officinalis*[26], Curcuma Oil (isolated from powdered rhizomes of *Curcuma longa* Linn)[27], *Ginkgo biloba* extract EGb761[28], and Cinnamophilin (isolated from *Cinnamomum philippinense*) [29], exhibit significant neuroprotective effects when they are administered before cerebral ischemia occurs, but the related mechanisms or targets have been identified for only a few. For instance, flavonoids from *Scutellaria baicalensis* Georgi, when either pretreated or post-treated, are demonstrated to decrease levels of malondialdehyde (MDA) and increase the level of superoxide dismutase (SOD) in the ischemic brains of mice. Aside from the anti-oxidant effects, flavonoids are also found to inhibit platelet aggregation, which is important to improve ischemic brain injury [25]. Pretreatment with curcuma oil, isolated from powdered rhizomes of *Curcuma longa* Linn, significantly reduces the levels of NO, ROS, ONOO⁻, and mitochondrial membrane potential [27].

Natural antioxidant compounds from various herbs protecting against cerebral ischemia have been reported in many recent studies. Some natural compounds exhibit direct regulatory effects on endogenous antioxidant enzyme systems. For example, Heme oxygenase (HO) is the rate-limiting enzyme for catabolism of the prooxidant heme. Two isoforms of HO exist: an inducible form (HO-1) and a constitutively expressed form (HO-2). HO-1 can be induced in response to various noxious stimuli (such as hypoxia and oxidative stress) and is considered a gene that protects against I/R injury[30-32]. CA, a catechol-type electrophilic compound found in the herb rosemary obtained from *Rosmarinus officinalis*, is shown to be neuroprotective when injected 1 h prior to MCAO in mice. As a representative electrophile, CA can induce the expression of a set of antioxidant enzymes, including heme oxygenase-1 (HO-1), NADPH quinone oxidoreductase 1 (NQO1), and c-glutamyl cysteine ligase (c-GCL). CAs become electrophilic quinones upon oxidation, with protective effects against neuronal oxidative stress and excitotoxicity via binding to specific Keap1 cysteine residues as a direct drug target, and then activating the Keap1/Nrf2 transcriptional pathway. The most attractive advantage of this agent is that it is a pro-electrophilic compound that can be activated by the microenvironment of oxidative stress and only becomes electrophilic at or near the site of ischemic brain tissues, with lower toxicity to normal tissues [26]. The protective effect of *Ginkgo biloba* extract on cerebral ischemia can be abolished in HO-1 knockout mice,

suggesting that HO-1 is the key target of neuroprotection against free radical damage [2, 28]. In cerebral ischemia, nitro oxide (NO) plays both a protective and a destructive role at different stages of this complex process. The beneficial effects of NO are related to the small amount of NO produced by endothelial nitric oxide synthase (eNOS), which produces significant effects on the maintenance of cerebral blood flow, prevention of neuronal injury by activation of the GC-cGMP-PKG pathway, and inhibition of platelet as well as leukocyte adhesion, and therefore protects against cerebral ischemia[33-34]. Refined Qing Kai Ling (RQKL), an improved injectable multi-component preparation derived from Qing Kai Ling, shows neuroprotection in MCAO rats by relieving vascular endothelial cell damage as well as inhibiting inflammation. More importantly, RQKL was able to stimulate the post-ischemic expression of eNOS, which might be an essential part of the neuroprotective mechanisms of RQKL [35]. However, the large amount of NO, which is derived from inducible nitric oxide synthase (iNOS), harms neurons by producing peroxynitrite after the reaction with superoxide. Peroxynitrite can inhibit the mitochondrial respiratory chain, which implicates the involvement of ATP loss and eventually leads to irreversible cellular damage [36-37]. Tetrahydroxystilbene glucoside (TSG), an active component of the rhizome extract from *Polygonum multiflorum*, has been reported to attenuate intracellular ROS generation and mitochondrial membrane potential dissipation caused by ischemia/ reperfusion. Interestingly, it can directly upregulate the expression of sirt1, which is a class III histone deacetyltransferase that promotes cell survival and subsequently reduces the expression and activity of iNOS. This in turn induces the increase in NO production as well as peroxynitrite formation and results in apoptotic cell death by inhibiting the phosphorylation and subsequent degradation of I- κ B, thereby hampering the DNA binding of nuclear factor kappa-B (NF- κ B) by sirt1 activation [38]. More evidence has emphasized the significance of sirt1 in promoting cell survival, regulating lifespan and inhibiting inflammation. Recently, sirt1 has been introduced for the therapy of neurodegenerative diseases [39-40].

The natural compounds like as resveratrol, butein and quercetin, which are known as anti-aging agents, have been found to directly activate sirt1[41], suggesting that sirt1 may be the direct target of many herbal components that exhibit anti-aging effects. Phosphoinositide 3-kinases (PI3K)/Akt regulate the survival response against oxidative stress-associated neuronal apoptosis, which is determined by the balance between the activity of PI3K and the phosphatase and tensin homolog (PTEN). Activation of Akt promotes cell survival and suppresses apoptosis by inhibition of several downstream substrates, including glycogen synthase kinase-3 β (GSK3 β). PTEN is a major negative regulator of the PI3K/Akt signaling pathway and has been demonstrated to act as an important mediator of ROS production and mitochondria-dependent apoptosis [42]. A recent study reveals that Baicalein (Bai), one flavonoid extracted from *Scutellaria baicalensis* Georgi, when administered either prior to or after ischemia, can significantly protect against brain injury. Similarly, incubation with Bai reverses the rapid PTEN dephosphorylation after oxygen glucose deprivation (OGD) in cultured hippocampal neurons. Npg PTEN siRNA largely abolished the protection of Bai against OGD-induced cell injury, which highlighted the critical role of PTEN signaling in Bai-mediated effects [43]. The cytoplasmic enzyme NADPH oxidase is another important target for ROS production in cerebral ischemia and has received increased attention in recent years. Excessive activation of the neuronal *N*-methyl-*D*-aspartate receptor (NMDAR) initiates superoxide formation and promotes neuronal death. Previous studies have suggested that mitochondria are the primary source of NMDAR-induced superoxide production, but there is

no definitive evidence. A recent study revealed that activation of NADPH oxidase is required for NMDAR-mediated superoxide production [44]. Interestingly, some natural compounds inhibit NADPH oxidase. For instance, sinomenine, an alkaloid extracted from a Chinese medicinal plant, *Sinomenium acutum*, which has been used widely in the clinic, apparently inhibits the activation of microglial NADPH oxidase [45]. The ethanol extract of *E rutaecarpa*, an anti-inflammatory drug commonly used in traditional Chinese medicine includes four bioactive compounds (dehydroevodiamine, evodiamine, rutaecarpine, and synephrine) and exhibits antioxidative effects by inhibiting NADPH oxidase activity [46]. These novel medicinal targets and mechanisms provide innovative clues and can help researchers to screen drugs for therapeutic intervention in ischemic brain injury mediated by natural antioxidants. Some natural antioxidant compounds exhibit therapeutic effects on brain ischemia in the clinic. For example, cinnamophilin, extracted from *Cinnamomum philippinense*, has been demonstrated to reduce brain infarction and improve neurobehavioral outcome when administered either 15 min before (pretreatment) or 2 h after the onset of middle cerebral artery occlusion (MCAO) (posts ischemic treatment)[29]. TSG also protected against brain injury at 2 h after cerebral ischemia [22]. A significant effect of curcuma oil (500 mg/kg body wt) given 4 h postischemia was also observed in a rat MCAO model [47]. These findings offer beneficial references for the application of natural antioxidants in clinical treatment of ischemia and related neuronal diseases.

Figure 3. Multiple signal pathways and potential targets involved in the neuroprotection of natural compounds.

Inflammation as a Target for Neuroprotection

Inflammation is obvious within several hours during ischemia/ reperfusion injury; it contributes to secondary damage caused by the microglial activation and resident perivascular and parenchymal macrophages, as well as infiltration of peripheral inflammatory cells [2]. A significant amount of the research on neuroprotection following stroke is concentrated on mitigating the effects of inflammation. An overview of the inflammatory process in the brain after stroke is shown in (Figure 4). Following ischemia and reperfusion, damaged brain tissue secretes cytokines and chemokines that recruit inflammatory cells to the injured area [48]. These cells release their own secretory factors, which can build up to toxic levels. Inflammatory processes also result in the production of reactive oxygen species, leading to oxidative stress and activation of matrixmetalloproteinases (MMPs), causing disruption of the blood-brain barrier (BBB) and edema.

On the other hand, inflammation has beneficial effects as well, such as increasing blood flow to the affected area and the removal of damaged tissue by phagocytic cells and MMPs. The positive versus negative effects of inflammation following stroke and the appropriateness of intervention are a topic that is often debated [49]. It is generally considered, however, that inflammation does more harm than good after stroke, especially in the early stages. One important molecule resulting in cell damage and death following stroke is tumor necrosis factor alpha (TNF α). TNF α interacts with two receptors, R1 and R2, that mediate death signals via the Fas associated death domain (FADD) and inflammation via the nuclear factor kappa-light-chain enhancer of activated B cells (NF κ B), respectively [50]. Activation of the NF κ B pathway is commonly used as an indicator of inflammation in stroke studies. The interleukins are another important set of molecules in the process of inflammation. Interleukin-1 (IL-1) is proinflammatory, whereas IL-10 is anti-inflammatory and IL-6 has both pro- and anti-inflammatory effects [51]. Antagonists of the IL-1 receptor have been shown to be neuroprotective when administered at reperfusion in comorbid tMCAO rats [52].

As one of the early initiators of inflammation after stroke, TNF α is an excellent target for neuroprotective treatments. Perhaps the most straightforward way to block the effects of TNF α is to prevent or reduce its production. The thalidomide analog 3,6 -dithiothalidomide (3,6 -DT) is an inhibitor of TNF α synthesis that has been shown to reduce the number of activated inflammatory cells in the brain after ischemic stroke in mice, as well as the extent of BBB disruption [53]. Caffeic acid ester fraction reduces infarct volume and improves performance on behavioral tests in rats subjected to MCAO [54]. Further experiments with cultured microglia suggest that this effect is due to inhibition of the production of TNF α , as well as nitric oxide (NO) and IL-1 β . Atorvastatin suppresses TNF α levels in a rat model of intracerebral hemorrhage, reducing brain water content and activation of microglia [55]. Another method of action against TNF α is the use of decoy receptors. Fusion proteins consisting of TNF receptor linked to a monoclonal antibody are capable of crossing the blood-brain barrier and significantly reduce infarct volumes after tMCAO in mice [56].

Activation of NF κ B by TNF α initiates a signaling cascade that regulates a number of inflammatory processes, making it a good point of intervention. Honokiol has been shown to suppress the activation of NF κ B in ischemic mice as well as levels of TNF α and significantly reduces brain water content [57]. Rosmarinic acid blocks activation of NF κ B by TNF α after tMCAO in diabetic rats and reduces edema and tissue damage [58]. Suppression of NF κ B

activity by angiotensin-(1–7) reduces infarct volumes, improves neurological deficits, and decreases oxidative stress in rats subjected to pMCAO [59]. Kaempferol glycosides inhibit the activation of NF κ B as well as the signal transducer and activator of transcription 3 (STAT3), another proinflammatory transcription factor, in tMCAO rats, resulting in reduced infarct volume and neurological deficits [60]. It should be noted that not all NF κ B activity is harmful, and harmful activation of the NF κ B complex is associated with abnormal acetylation of the RelA subunit. Using a combination of an inhibitor of one type of deacetylase and an activator of another, it is possible to produce a RelA acetylation similar to that seen in the beneficial phenomenon known as ischemic preconditioning, resulting in neuroprotection in mice exposed to tMCAO [61].

The various signaling cascades induced by stroke lead to the activation and recruitment of inflammatory cells to the site of injury. In the early stages of stroke, prior to the infiltration of neutrophils and macrophages from other locations, resident microglia are the primary inflammatory cells in the brain. Microglia continue to be involved well into long term recovery and have been observed 28 days following stroke in MCAO rats [62]. Although microglia serve a beneficial purpose by removing dead tissue, they also release secretory factors that can accumulate to toxic levels, particularly in cases of excess activation such as stroke.

Figure 4. Damaging inflammatory mechanisms in stroke. Proinflammatory cytokines and reactive oxygen species released by damaged neurons lead to the activation of microglia and the expression of cellular adhesion molecules on endothelial cells and migrating inflammatory cells. Infiltrating inflammatory cells and activated microglia secrete additional cytokines and oxygen species, resulting in further tissue damage, oxidative stress, and activation of matrix metalloproteinases leading to disruption of the blood-brain barrier and edema.

Accordingly, treatments that limit microglial activation often have neuroprotective effects. The ginseng metabolite compound K suppresses microglial activation by inhibiting multiple upstream signaling molecules and is neuroprotective in MCAO mice [63]. Sesamin is neuroprotective in a mouse model of ICH and has been shown to prevent an increase in microglial cells by keeping them in their resting state [64].

Retinoids are also neuroprotective in models of ICH and reduce levels of activated microglia even with posttreatment [65]. Alternatively, increasing the reactivity of microglia can also have neuroprotective effects. The ATP-dependent potassium channel blocker glibenclamide increases the phagocytic capacity of microglia, resulting in improved neurological outcome, reduced infarct volume, and enhanced neurogenesis in rats subjected to transient or permanent MCAO [66-68]. Activation of the microglial α -7 nicotinic acetylcholine receptor induces expression of the heme oxygenase-1 (HO-1) gene, which is associated with neuroprotection in mice after photothrombotic stroke [69].

The processes involved in inflammation may not only directly contribute to brain damage following stroke but may also activate secondary mechanisms that lead to further damage. The activity of large numbers of inflammatory cells in the affected area, combined with low oxygen and ATP levels, leads to the formation of reactive oxygen species and the onset of oxidative stress. Activation of MMPs, while important for the removal of dead tissue and the ability of immune cells to enter the brain, may also result in disruption of the blood-brain barrier and edema due to an influx of water. These topics will be discussed separately in the following sections.

Natural Compounds with Anti-Inflammatory Effects

Inflammation is obvious within several hours during ischemia/ reperfusion injury; it contributes to secondary damage caused by the microglial activation and resident perivascular and parenchymal macrophages, as well as infiltration of peripheral inflammatory cells. Aside from regulation of inflammation at the molecular level, progressive ischemic brain injury is related to several post-injury inflammatory responses at the cellular level, including neutrophil response as early as 4 h after ischemia/reperfusion and delayed macrophage infiltration, which occurs several days later [2]. Sufficient evidence has indicated that neutrophils play a key role in the development of ischemic brain damage, and the depletion of circulating neutrophils or inhibition of neutrophil infiltration is demonstrated to ameliorate ischemic cerebral injury [70]. Thus, more and more evidence suggests that anti-inflammatory treatment might reduce ischemic brain injury and facilitate recovery [71]. Many bioactive components from Chinese medicinal plants exhibit significant anti-inflammatory effects, and recent studies have revealed that some exhibit neuroprotection against cerebral ischemia. Such compounds include theaflavin [72], Wogonin (a flavonoid derived from the root of a medicinal herb, *Scutellaria baicalensis* Georgi)[73], and *Graptopetalum paraguayense* E Walther leaf extracts[74]. Pretreatment with these bioactive components diminishes microgliamediated inflammatory activity and neutrophil responses after brain ischemia.

Figure 5. Mechanisms of induction of apoptosis. In the classical pathway, mitochondria release cytochrome C in response to cell stress and damage, leading to activation of caspase 9 and subsequent activation of caspase 3 and other effectors of apoptosis. Alternatively, mitochondria may also release apoptosis-inducing factor (AIF), which leads to apoptosis by a caspase independent mechanism. The death receptor pathway involves the activation of FADD by various cell signal receptors, followed by activation of caspase 8 and the subsequent caspase cascade leading to apoptosis.

Few studies have elucidated in detail the precise target for natural anti-inflammatory agents used to treat cerebral ischemia, suggesting that its precise mechanism of neuroprotection is still far from definite. Recently, several new targets closely related to inflammation, such as peroxisome proliferator- activated receptor- γ (PPAR γ) and NF- κ B, have been reported to mediate inflammation in activated macrophages by regulation of gene promoter regions, leading to inflammatory gene transcription [75]. Some plant-derived compounds exhibit direct regulation of PPAR γ and NF- κ B. For example, unique polychlorinated compounds named chlorophyllins A-C exhibit potent PPAR γ agonistic effects [76] and prenyloxycinnamic acid derivative 4'-geranyloxyferulic acid, obtained from *Acronychia baueri* Schott, also increases PPAR γ activity significantly [77]. Incensole acetate and its nonacetylated form, incensole (IN), isolated from *Boswellia* Resin, a major anti-inflammatory agent in the herbal medical tradition, inhibits NF- κ B activation [78]. The anti-inflammatory compound parthenolide from the medicinal herb Feverfew (*Tanacetum parthenium*) directly binds to and inhibits I- κ B kinase [79]. Hesperetin, a flavanone derived from citrus fruits, suppresses NF- κ B activation in both young and old rats through multiple signal transduction pathways [80]. These exciting studies indicate that nuclear transcription factors may serve as the direct target of natural anti-inflammatory compounds. More attention should be paid to the role of these transcription factors in the neuroprotective effects of natural anti-inflammatory compounds.

Apoptosis as a Target for Neuroprotection

During stroke, the diminished supply of oxygen and glucose to the brain leads to reduced cellular metabolism and depletion of energy stores. Combined with tissue damage due to mechanisms such as those mentioned above, cell death by either necrosis or apoptosis may be initiated. In the context of intervention, apoptosis is preferable to necrosis because it can be blocked by various treatments, allowing damaged tissue to be rescued. Cells within the core infarct typically die by necrosis, whereas those in the penumbra die by apoptosis. The primary factor in determining which mechanism of cell death occurs is the level of ATP within the cell [81]. ATP is required for the process of apoptosis, and cells with insufficient ATP stores will die by necrosis instead. Apoptosis can occur by several pathways, as shown in Figure 5.

The mitochondrial pathway can proceed through either caspase dependent or caspase independent mechanisms. Alternatively, apoptosis may be induced by the death receptor pathway. In the caspase dependent pathway of mitochondrial apoptosis, release of cytochrome C from mitochondria results in activation of caspase 3, which initiates a caspase cascade leading to the degradation of cellular components and cell death. Caspase 3 activity is commonly used as an indicator of apoptosis. Reduction of activated caspase 3 levels is therefore a goal of many neuroprotective treatments. Tanshinone IIA decreases the levels of cleaved caspase 3 in tMCAO rats, resulting in a reduction in infarct volume, edema, and neurological deficits. Diallyl sulfide reduces expression of caspase 3 and increases expression of BCL-2, an endogenous antiapoptotic protein, in tMCAO rats as well. Hypothermia has been shown to reduce caspase 3 levels for up to 1 week after focal cerebral ischemia in rats [82]. Pioglitazone, an agonist of the peroxisome proliferator-activated receptor γ (PPAR γ), activates STAT3 in tMCAO rats, leading to changes in the expression of antiapoptotic genes and reduced levels of caspase 3 [83]. Caspase 3 is not the only potential therapeutic target within this pathway, however. The cellular inhibitors of apoptosis (cIAPs) are endogenous molecules that bind to caspases and block their activation. Ischemic preconditioning has been shown to increase the levels of cIAP1 in neurons and reduce apoptosis following unilateral CCAO in rats [84].

Although apoptosis is most commonly associated with the caspase dependent mitochondrial pathway, other pathways also contribute to cell death after stroke, and neuroprotective agents that act upon these pathways are being investigated. The caspase independent pathway of apoptosis is characterized by mitochondrial release of apoptosis-inducing factor (AIF), which is stimulated by the activity of poly(ADPribose) polymerase (PARP). Several treatments that inhibit the caspase dependent pathway of apoptosis have also been shown to inhibit the caspase independent pathway as well. Ethanol administration decreases the expression of both caspase 3 and AIF up to 24 hours after tMCAO in rats [85]. The nitric oxide donor (S)-ZJM-289 suppresses the release of both cytochrome C and AIF from mitochondria and significantly reduces injury in MCAO rats [86]. Cyclosporin A has been shown to decrease the expression of caspase 3, AIF, and cytochrome C in a rat model of SAH [87].

Some compounds have been identified recently that target caspase independent pathway specifically. Ginsenoside-Rd has been shown to inhibit PARP-1 activity and AIF release in rats subjected to MCAO [88]. The death receptor pathway of apoptosis differs from the other two in that mitochondria are not required for its induction. Similar to the caspase dependent pathway of mitochondrial apoptosis, however, the death receptor pathway also uses caspase 3

as an effector. Treatments that affect the level and activity of caspase 3 may therefore block this pathway as well. Treatments that target this pathway directly have also been identified. Muscone decreases the expression of the death receptor FAS and reduces apoptosis in MCAO rats [89]. Antibodies against TNF α , another initiator of the death receptor pathway, block changes in the expression of caspase 3 after SAH in rats [90].

Natural compounds with anti-apoptotic effects

Ischemic cerebral injury is known to induce histopathological damage and related neurological deficits, leading to the activation of complex neurochemical cascades of cell death, which are primarily expressed as apoptosis. In principle, these apoptotic cascades are reversible and form an important aspect of the penumbra concept, a major target of therapeutic interventions. In general, ischemia and reperfusion induced neuronal apoptosis can be classified into two types: caspase-dependent and caspase-independent pathways. Caspases are intracellular proteases that function as initiators and effectors of apoptosis. When activated, caspases cleave a variety of intracellular proteins, including major structural elements in the cytoplasm and nucleus, components of the DNA repair machinery, and a number of protein kinases [91]. Thus, caspases may be effective against ischemia-induced neuronal cell apoptosis by blocking apoptotic cascades with appropriate drugs. An alkaloid-free ethyl acetate, extracted from the root of *Sophora flavescens*, has been reported to protect against focal cerebral ischemia by decreasing DNA fragmentation and inhibiting caspase-3 activity directly [92]. In that study, it was found that caspase-independent programmed cell death, mediated by the translocation of apoptosis-inducing factor (AIF) from the mitochondria to the nucleus, plays a key role in ischemia. During ischemia and reperfusion injury, in the case of massive and irreparable DNA damage, overactivation of Poly(ADP-ribose) Polymerase-1 (PARP-1) can lead to necrotic cell death caused by the depletion of NAD⁺ and ATP, as well as enhance AIF release from mitochondria [93]. A series of PARP-1 antagonists have been developed, some of which have become promising drug candidates [94-95]. However, the characterization of natural compounds regulating PARP-1 remains to be elucidated.

It is thought that berberine performs its anti-apoptotic effect by inhibiting both caspase-dependent and independent pathways [96]. Synergistic inhibition of caspase-dependent and independent neuronal cell apoptosis is more likely to be effective as a therapeutic approach for the treatment of ischemia. Numerous herb drugs have been demonstrated to act on anti-apoptotic pathways, such as Bcl-2 family proteins. The abundant expression of Bcl-xL protein in the adult brain is known to suppress activation of procaspase 9 by forming a complex with Apaf1 and to prevent the release of cytochrome c from mitochondria, thus maintaining cell viability. Therefore, Bcl-xL becomes a promising target for drug intervention to reduce cell apoptosis [97]. Pretreatment with 4-hydroxybenzyl alcohol 30 min before ischemia, one of the major active phenolic constituents of *Gastrodia elata* Blume, could antagonize cerebral ischemia by increasing Bcl-2 expression and inhibiting caspase-3 activity, leading to the amelioration of cell apoptosis in ischemic regions [98]. Direct evidence from preclinical research shows that Ginsenoside Rb1 (gRb1) regulates the anti-apoptosis signaling pathway, which stimulates the expression of mitochondrion-associated anti-apoptotic factor Bcl-xL through the use of reporter plasmids. The transcription factor signal transducer and activator of transcription 5 (Stat5) are known to activate Bcl-xL family proteins via binding to the bcl-xL promoter. The Stat5 responsive element in the bcl-xL promoter becomes active in

response to gRb1 treatment, suggesting that the Stat5 pathway participates in anti-apoptotic effects by regulating Bcl-2 indirectly through activation of gRb1 [99]. Molecular pharmacology research in this direction should elucidate the direct target of natural drugs that regulate apoptotic signaling pathways.

Excitotoxicity as Target for Neuroprotection

During stroke, depletion of neuronal oxygen and energy reserves leads to the release of toxic amounts of the neurotransmitter glutamate into the extracellular space [100-101]. The subsequent activation of glutamate receptors causes an influx of calcium and neuronal depolarization, resulting in aberrant activation of numerous calcium-dependent pathways in the brain and initiation of the processes of necrosis, apoptosis, and autophagy. Glutamate excitotoxicity therefore plays a significant role in the pathology of stroke, and a large number of research studies are devoted to suppressing its effects. One method of neuroprotection against excitotoxicity is to reduce the amount of glutamate release during stroke. The *Ginkgo biloba* extract EGb761 has been shown to significantly decrease striatal glutamate levels in mice subjected to MCAO, accompanied by reduced neurodegeneration and edema [102]. The individual constituents of EGb761 also have neuroprotective properties [103]. Another method of protection is to block the action of glutamate receptors in the brain. The microRNA miR-223 reduces expression of the glutamate receptor subunits GluR2 and NR2B, and is neuroprotective against transient global ischemia [104]. Activation of the transient receptor potential vanilloid 4 (TRPV4) is associated with increased activity of the NMDA receptor. HC-067047, an antagonist of TRPV4, reduces the extent of infarct after tMCAO in mice [105]. Magnesium sulfate is an antagonist of the N-methyl-D-aspartate (NMDA) subtype of glutamate receptor and in some studies has been shown to improve recovery in humans with acute ischemic stroke [106]. On the other hand, large scale clinical trials such as the intravenous magnesium efficacy in stroke (IMAGES) trial concluded that magnesium did not significantly improve outcome in ischemic stroke patients but may be beneficial in lacunar stroke [107]. It is possible that the timing of treatment is critical; therefore the field administration of stroke therapy-magnesium (FAST-MAG) trial was devised to test the benefits of magnesium given prior to arrival at a hospital.

Results from a pilot trial suggest that early administration of magnesium may have benefits, and phase III trials are currently underway [108]. Inhibiting the influx of calcium into cells following glutamate receptor activation can also be beneficial. Overexpression of the transient receptor potential canonical 6 (TRPC6) suppresses the increase in calcium induced by NMDA and reduces infarct size and mortality in mice [109]. Hyperforin, an activator of TRPC6, has also been found to be neuroprotective following tMCAO in rats [110]. The compound ginsenoside-Rd decreases expression of the calcium channel TRPM7 in MCAO rats, which may be partially responsible for its neuroprotective effects [111].

Natural compounds with calcium antagonization (Excitotoxicity)

ROS bursts and excitatory amino acid toxicity caused by ischemic reperfusion will lead to intracellular Ca^{2+} overload. Ca^{2+} overload in neurons is an essential signal of catastrophic events leading to irreversible neuronal injury. As a result, effects of herb components on Ca^{2+} overload induced by ischemic reperfusion have been studied extensively. Some herb components, for example, guattegaumerine (bisbenzylisoquinoline alkaloid from *Guatteria gaumeri*) and TSG, are found to reduce ischemia induced Ca^{2+} overload in neurons [112].

However, the exact mechanisms have not been elucidated in most studies. The main pathways of Ca^{2+} overload after cerebral ischemia and reperfusion are as follows: 1) the depletion of ATP leads to inactivation of Na^+, K^+ -ATPase, an enzyme regulating ionic concentration gradients for the generation of action potentials in neurons, with resultant depolarization of cell membrane potential and further opening of Ca^{2+} -permeable cation channels such as voltage-gated calcium channels (VGCCs)[113]; 2) the abundant release of excitatory amino acid activates α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors, thereby further depolarizing the cell membrane potential and resulting in massive activation of NMDAR[114]; 3) the activation of NMDAR induces NADPH oxidase-or mitochondria pathway-dependent ROS generation, with subsequent Ca^{2+} release from intracellular calcium stores and influx through transient receptor potential melastatin (TRPM) channels, mediating ROS-dependant Ca^{2+} overload[115]; 4) extracellular acidulation could activate some acid-sensing ion channels and receptors, especially the Ca^{2+} permeable acid-sensing ion channel 1a (ASIC1a)[116]. Honokiol, a component of the herb *Magnolia officinalis*, can attenuate the decrease in Na^+, K^+ -ATPase activities induced by MCAO, but it has not been clarified whether the agent exhibits its effect by acting directly on Na^+, K^+ -ATPase or by attenuating the pathological inducer [117]. Use of VGCC blockers has been considered a therapeutic approach for post-stroke neuroprotection in humans for many years. Previous studies have shown that some isoquinoline alkaloids contained in medicinal herbs such as berberine (an alkaloid derived from the herbal medicine *Rhizoma coptidis* and palmatine (a flavonoid in propolis) exhibit significant and rapid inhibition of voltage-gated calcium currents in many native cells [118]. Interestingly, some of these alkaloids also exhibit neuroprotective effects against several central nervous system diseases [119].

There are few reports about the direct inhibition of NMDA receptor by natural products. Recently, some cation channels closely related to Ca^{2+} overload and selectively activated in certain pathological conditions have been a focus of drug development, including ASICs and TRPM. ASICs, especially ASIC1, which has been reported to be activated by extracellular acidosis, play a key role in ischemic cerebral injury [120]. In recent studies, puerarin, extract from *Radix puerariae*, has been reported to inhibit ASICs current in both natural cells and transfected cells, indicating the advantages of isolating novel ASIC antagonists with low toxicity from natural products [121]. Inhibition of TRPM, a Ca^{2+} -permeable nonselective cation channel, increases the resistance of neurons to ischemic death after brain ischemia and then preserves neuronal morphology and function. At present, several lines of evidence have demonstrated that accumulation of ADP-ribose induced by oxidative stress has led to the rapid opening of TRPM2 channels and calcium influx. TRPM2 might be the major pathway of cellular calcium overload induced by oxidation. Blockade of TRPM2 could reduce the cellular injury induced by oxidation. However, few research efforts have been conducted to explore compounds isolated from natural products that antagonize ADP-ribose or block TRPM2 channels [122-123].

Certain natural drugs are able to decrease the intracellular Ca^{2+} overload induced by oxidation. For example, salvianolic acid B, isolated from *Radix Salviae miltiorrhizae*, protects PC12 cells against hydrogen peroxide-induced intracellular calcium overload [124]. More interestingly, the structure-activity relationship of quercetin, which is abundant in various fruits and vegetables such as apple and carrot, as well as red wine and tea, has been revealed to antagonize hydrogen peroxide-induced calcium dysregulation in PC12 cells [125]. In one study, hydrogen peroxide induced an intracellular calcium elevation that could not recover the

Ca²⁺ levels in PC12 cells, but quercetin antagonized the effects of hydrogen peroxide in that cell model. Structure-activity relationships of five flavonoids were examined and the results indicate that two structural components, including (i) 3',4'-hydroxyl (OH) groups in the B ring and (ii) a 2,3-double bond in conjugation with a 4-oxo group in the C ring, as well as the polyphenolic structures, are crucial for the protective effect. Based on the significance of TRPM channels in calcium overload induced by oxidation, more attention should be paid to the natural compounds that antagonize hydrogen peroxide-induced calcium dysregulation by regulation of TRPM channels. These studies indicate that the natural products that can antagonize the ischemia-induced calcium overload might act on these novel targets involving ASICs and TRPM channels rather than on traditional targets such as L-type calcium channels and NMDA receptors. Nevertheless, more evidence and further studies are necessary to support this hypothesis.

Blood-Brain Barrier Disruption as a target for neuroprotection

Disruption of the bloodbrain barrier following stroke is commonly associated with the action of two matrix metalloproteinases, MMP-2 and MMP-9. MMP-2 is constitutively expressed at low levels in normal brain tissue; however stroke increases its expression and activity and also induces the expression of MMP-9. MMP-2 cleaves and activates MMP-9, which degrades components of the basement membrane in vascular walls and leads to BBB disruption. Other factors involved in BBB permeability after stroke include the extent of tight junction formation between endothelial cells and the effects of treatment with tissue plasminogen activator. The activity of MMPs is regulated endogenously by the tissue inhibitor of matrix metalloproteinase (TIMP), and treatments that stimulate it may be of significant benefit in protection against stroke-related brain damage. Inhibition of the expression and activity of MMPs by other means may be protective as well. Ethanol has been shown to inhibit the increase in MMP-2 and MMP-9 expression after tMCAO in rats and significantly reduces brain edema [126]. *Apocynum venetum* leaf extract (AVLE) also alleviates symptoms of BBB disruption in tMCAO rats by inhibiting the expression and activity of MMPs [127]. Hyperbaric oxygen treatment improved BBB function in a rat embolic stroke model through modulation of MMP-9 but displayed reduced effectiveness when administered in combination with tPA [128]. It may therefore be of limited benefit in those stroke patients who receive tPA.

Treatments that increase the formation of tight junctions may also provide neuroprotection following stroke. Doxycycline increases the expression of tight junction proteins in tMCAO rats and also inhibits MMPs [129]. Kruppel-like factor 2 (KLF2) protects against tMCAO in mice by regulation of the tight junction component occluding [130]. The c-Jun Nterminal kinase (JNK) inhibitor SP600125 restores vascular tight junctions and alleviates BBB disruption in a rat model of subarachnoid hemorrhage [131]. The GTPase RhoA is known to play an important role in the regulation of endothelial tight junctions, and inhibition of RhoA by fibroblast growth factor preserves BBB integrity in a mouse model of intracerebral hemorrhage [132]. Additional neuroprotective strategies include those that alleviate the negative effects of tPA. High density lipoproteins have been shown to reduce hemorrhagic transformation and improve BBB integrity following tPA treatment in experimental models [133]. Neurotrophic factors can also be used to stimulate repair mechanisms and restore BBB function. Pigment epithelium-derived factor (PEDF), for example, has been shown to have

beneficial effects on both BBB permeability and lesion volume after ischemiareperfusion in rats [134].

Disruption of the blood–brain barrier occurs after stroke. Therefore, protection of the blood–brain barrier has become an important target of stroke interventions in experimental therapeutics. Whether curcumin prevents cerebral ischemia/reperfusion injury by protecting blood–brain barrier integrity was investigated in one study [135]. A single injection of curcumin (1 or 2 mg/kg, i.v.) for 30 min after focal cerebral ischemia/reperfusion in rats significantly diminished infarct volume, improved neurological deficit, decreased mortality, and reduced the water content of the brain. Further experiments using cultured astrocytes found that curcumin significantly inhibited inducible nitric oxide synthase (iNOS) expression and NO_x (nitrites/nitrates contents) production induced by lipopolysaccharide (LPS)/tumor necrosis factor- α (TNF- α). Curcumin also prevented ONOO[–] donor SIN-1-induced cerebral capillary endothelial cell damage. On the basis of these observations, the authors concluded that curcumin can ameliorate cerebral ischemia/reperfusion injury by preventing ONOO[–]-mediated blood–brain barrier damage. Curcumin treatment also decreased malondialdehyde levels, cytochrome c, and cleaved caspase-3 expression and increased mitochondrial Bcl-2 expression. These authors concluded that the neuroprotective action of curcumin is exerted by antiapoptotic mechanisms. Similarly, curcumin was shown as a potent neuroprotective agent against stroke in a number of related studies [137–139]. Some other nutraceuticals with potential as antistroke agents include allicin, apigenin, kaempferol, quercetin and sulforaphane [140–144].

Benefits of Combination Therapy for Neuroprotection in Stroke

The pathology of stroke is complex, with multiple overlapping processes leading to either damage or protection. Although considerable neuroprotection can be gained by targeting just one of these processes, the potential benefit is even greater if multiple mechanisms of damage can be suppressed at the same time. Targeting the same pathway with more than one neuroprotective agent can also be beneficial. Consequently, combination therapy with more than one drug has proven to be effective in several experimental studies. The additional benefit may be small, additive, or even synergistic in some cases. Progesterone plus vitamin D hormone, for example, reduces infarct size and neurological deficits in tMCAO rats to a greater extent than either treatment alone [145]. The combination of the anti-inflammatory properties of atorvastatin and the antioxidant properties of probucol also produces increased neuroprotection in pMCAO rats [146]. Simvastatin combined with granulocyte colony-stimulating factor (G-CSF) reduced recovery time in a rat model of intracerebral hemorrhage and improved outcome [147]. Another strategy for combination therapy is the use of one drug to block the negative effects of another, such as tPA. Mild hypothermia, high-density lipoproteins, activated protein C analog, and fingolimod have all been shown to reduce the incidence of hemorrhagic transformation following administration of tPA in several animal models [148–150].

Neuroprotective Treatments with Pleiotropic Effects

Although combination therapy can produce additional benefits in some cases, not all treatments are compatible with each other. Some combinations may have antagonistic effects, producing less benefit than either treatment alone. In some cases, combination therapies may enhance damage. Furthermore, combination treatment requires significantly more testing to

determine safety and effectiveness than a single compound. There is therefore considerable interest in the study of treatments with beneficial effects on more than one mechanism of stroke-related damage. Some of these treatments have only recently been discovered (Table 1) and are still in the early stages of investigation. Others, however, have already been the subject of considerable study and show great promise for the treatment of stroke, as summarized below.

Minocycline. Minocycline is a broad spectrum antibiotic which, in addition to its antibacterial activity, also has anti-inflammatory and antiapoptotic effects [151]. Consequently, it has been shown to be protective in a number of diseases including stroke. Minocycline is one of the few neuroprotective agents in animal studies that has also been proven effective in human trials. In one recent trial, oral administration of minocycline resulted in significantly improved outcomes as long as three months after stroke [152]. Furthermore, animal studies indicate that additional benefits are to be gained by combining minocycline with other neuroprotective strategies. Minocycline reduces the risk of subsequent hemorrhage following administration of tissue plasminogen activator in diabetic rats subjected to focal embolic stroke [153]. It also reduces infarct size and suppresses several hallmarks of inflammation. Minocycline plus normobaric hyperoxia has a synergistic effect on the reduction in infarct volume following tMCAO in rats and has a positive effect on hemispheric swelling that was not seen with either treatment alone [154]. This combination also resulted in greater inhibition of apoptosis and MMP activation. Minocycline improves recovery after transplantation of bone marrow mononuclear cells into ischemic rats, presumably by inhibition of microglial activation [155-156]. It also preconditions neural stem cells against oxidative stress, producing reduced infarct size and improved neurological performance following transplantation in rats exposed to tMCAO [157].

Carnosine. Carnosine is a naturally occurring dipeptide that has both antioxidant and antiexcitotoxic properties [158-159]. It also is an efficient chelator of metal ions such as zinc, which is required for the activity of matrix metalloproteinases. Preclinical studies have shown that carnosine is well tolerated and produces robust neuroprotection in animal models of both transient and permanent ischemia [160]. It also readily crosses the intact blood-brain barrier, which allows it to be administered even in the early stages of stroke. Carnosine reduces glutamate excitotoxicity in pMCAO mice, resulting in reduced infarct size and improved neurologic function [161]. In another study, carnosine was shown to decrease infarct size, MMP activity, and levels of reactive oxygen species [162]. Carnosine can also be cleaved by carnosinase into the amino acids alanine and histidine, which are neuroprotective as well. Bestatin, an inhibitor of carnosinase, increases damage in pMCAO mice [163].

Asiatic Acid. Asiatic acid is a plant-derived compound with effects on oxidative stress, inflammation, and excitotoxicity that has been shown to be beneficial in the treatment of wound healing, beta-amyloid toxicity, and liver injury. Recent evidence suggests that it may be neuroprotective in stroke as well. In pMCAO mice, asiatic acid reduces infarct size and improves neurologic scores, possibly by suppression of mitochondrial damage and BBB disruption [164]. Subsequently, asiatic acid was also found to be neuroprotective in multiple models of ischemia in rats by inhibiting mitochondrial damage and MMP-9 activation [165]. Asiatic acid also blocks the negative effects of excitotoxicity in mice following exposure to glutamate [166]. An extract of *Centella asiatica* has been shown to improve several markers of behavioral function and improved the antioxidant status in tMCAO rats [167]. This extract

contains asiatic acid as well as several other related compounds that also have neuroprotective properties. Further investigation of this class of molecules is therefore warranted to determine the extent of their effects.

Cannabinoids. Another major class of molecules with multiple beneficial effects in stroke are the cannabinoids. These compounds are primarily known for their anti-inflammatory effects in many diseases including stroke [168]. Recently, however, evidence suggests that cannabinoids may also have antioxidant and antiapoptotic effects [169]. The cannabinoid receptor agonists WIN55,212-2 and JWH-133 reduce activation of microglia and macrophages after induction of ischemia in mice and rats, resulting in reduced infarct size and neurological impairment, as well as protection of oligodendrocyte precursor cells [170–171]. Another receptor agonist, TAK-937, provides neuroprotection in tMCAO rats, and the neuroprotective effect is increased when given in combination with hypothermia [172]. Furthermore, TAK-937 not only is effective in rodent models of stroke but also has been shown to reduce infarct volume in nonhuman primates [173]. This specific compound is therefore of considerable interest for future use in human trials.

Flavonoids. In some cases, whole classes of molecules are known for having multiple neuroprotective effects. One such group of compounds that are currently the subject of intensive research are the flavonoids. These molecules are naturally occurring compounds that readily cross the blood-brain barrier and are well known for their protective effects. The flavonoids in cocoa, for example, have antioxidant properties and also promote perfusion, angiogenesis, and neurogenesis in the brain [174]. Xanthohumol has been found to have anti-inflammatory, anti-apoptotic, antioxidant, and antithrombotic properties. Following MCAO in rats, xanthohumol decreases the levels of TNF α , hypoxia-inducible factor 1 α (HIF-1 α), and inducible nitric oxide synthase (iNOS) [175]. It also reduces expression of activated caspase 3, scavenges hydroxyl radicals, and inhibits platelet aggregation. Treatment with naringenin results in neuroprotection in tMCAO rats through both antioxidant and anti-inflammatory mechanisms [176]. Galangin improves cerebral blood flow, inhibits apoptosis, and protects mitochondrial function after MCAO in rats [177]. In tMCAO mice, fisetin protects the brain against ischemic injury by suppressing activation of cerebral inflammatory cells and inhibiting the migration of macrophages and dendritic cells into the brain [178]. In models of intracerebral hemorrhage, baicalin has been found to attenuate edema of the brain and inhibit apoptosis [179].

Neuroprotective Agents in Human Clinical Stroke Trials

Perhaps the greatest challenge in the study of neuroprotection in stroke is the translation of animal studies to humans. Numerous treatments that produce robust protection in rodents have failed to provide significant benefit in clinical trials. The various theories on the reason for this failure have already been discussed elsewhere and will not be covered here [180–181]. Amid the abundance of discouraging results, however, a small number of neuroprotective strategies have shown promise in human stroke patients. A brief summary of recently completed clinical trials for the study of neuroprotection in ischemic stroke and subarachnoid hemorrhage is provided below.

Citicoline Trial on Acute Stroke (ICTUS)

Citicoline is a nutritional supplement that not only is commonly used to improve memory retention but also has been shown to prevent neuronal degeneration and improve visual

function. It has already been approved in some countries for the treatment of acute ischemic stroke. A randomized, placebo controlled trial was conducted to evaluate the efficacy of citicoline in patients with moderate to severe acute ischemic stroke [182]. A total of 2298 patients were administered either citicoline (1000 mg every 12 hours) or placebo for up to 6 weeks. Outcome was determined at 90 days based on the National Institute of Health Stroke Scale (NIHSS), modified Rankin Scale (mRS), and modified Barthel Index (mBI scores), plus the occurrence of intracranial hemorrhage, neurologic deterioration, or death. No significant difference in recovery was observed between the citicoline and placebo treatment groups.

Ginsenoside-Rd. Ginsenoside-Rd is a calcium channel antagonist that has been previously shown to be neuroprotective in human trials. An extended trial of ginsenoside-Rd was performed in 390 patients with acute ischemic stroke [183]. Subjects were administered ginsenoside-Rd or placebo intravenously over a 14-day period and evaluated using NIHSS and mRS scores for 90 days. Significant improvement was seen with ginsenoside-Rd in NIHSS scores at 15 days and mRS scores at 90 days.

Cerebrolysin. Cerebrolysin is a mixture of peptide fragments that mimics the action of neurotrophic factors and has been shown to be neuroprotective in a number of conditions such as hyperthermia-induced neurotoxicity, vascular dementia, Alzheimer's disease, traumatic brain injury, and stroke. A large, double-blind clinical trial was conducted to test the efficacy and safety of Cerebrolysin in patients with acute ischemic stroke [184]. A total of 1070 patients were administered aspirin and either Cerebrolysin (30 mL/day) or placebo over a period of 10 days. Although no significant difference between treatment groups was seen after 90 days, a positive trend was seen in those patients with an NIHSS score greater than 12.

Minocycline. Minocycline is an oral antibiotic with proven safety over years of use. In addition to its antibiotic properties, minocycline also has anti-inflammatory and antiapoptotic effects that have been shown to be neuroprotective in animal models of stroke and in previous human trials. The efficacy of oral minocycline was examined in a recent single-blinded open-label study [185]. Fifty patients with acute ischemic stroke were given either minocycline (200mg/day) or placebo for five days and assessed for various indicators of outcome at 1, 7, 30, and 90 days. Patients receiving minocycline showed significant improvement after 30 days in NIHSS, mBI, and mRS scores. NIHSS scores continued to be significantly improved at 90 days. Larger phase II and phase III trials are awaited.

Summary

The pathology of stroke is incredibly complex, and treatment of its devastating effects is a continuing medical challenge. The topic of neuroprotection in stroke is equally complex, as can be seen by the wide variety of approaches currently being studied by the scientific community. On the one hand, no treatment or combination of treatments can be expected to encompass the entirety of damaging processes that occur during stroke. In this respect, the search for better therapies is never ending. On other hand, the availability of a large number of neuroprotective strategies increases the probability that one or more will ultimately prove to be effective. This fact is particularly relevant considering that the largemajority of neuroprotective treatments developed in animal models have failed to produce significant benefits in human trials. As a result, treatment options for stroke are still limited. A few neuroprotective agents have shown promise, however, and it is hopeful that they may be approved for general use in the future.

The failure of preclinical studies to translate into clinical trials highlights the importance that these studies be properly designed. To this end, the Stroke Therapy Academic Industry Roundtable (STAIR) has developed a set of recommendations for the preclinical assessment of neuroprotective treatments [186]. These include consideration of the proper animal model, dosage level, and time points to be used, as well as the use of physiological monitoring and more than one measure of outcome. Recommendations for phase I/II clinical trials of potential stroke therapies have also been developed to facilitate the transition to phase III trials [187]. It is critical that both preclinical studies and clinical trials be designed to complement one another, in order to ensure that the results are comparable and to allow subsequent investigation of the reasons behind the success or failure of neuroprotective treatments in humans. It has also been proposed that, rather than proceeding directly from animal studies to clinical trials, international multicenter preclinical studies should be performed on promising neuroprotective agents to identify potential problems in translating from animals to humans [188-189].

Figure 6. Structures of polyphenols. Polyphenols are a group of naturally occurring phytochemicals which are present in high amounts in fruits, vegetables, and natural products and are characterised by the presence of multiple hydroxyl groups on aromatic rings. These compounds are divided into two main categories, the flavonoids and non flavonoids, based on the number of phenol rings and the way in which these rings interact. For the flavonoid group, the major differences between the individual groups arise from the hydroxylation pattern of the ring-structure, the degree of saturation of the C-ring, and the substitution of the 3-position. HBAs, hydroxybenzoic acids; HCAs, hydroxycinnamic acids.

One complicating factor in the development of neuroprotective strategies is the dual nature of many of the processes that occur in the brain during stroke. The activity of MMPs, microglia, and other inflammatory cells, for example, can be either damaging or protective depending on the magnitude, location, and timing of their effects. Even mechanisms of cell death such as apoptosis and autophagy can be beneficial in the right circumstances. The development of potential neuroprotective treatments, therefore, must take both the positive and negative aspects of the stroke response into consideration, to ensure that they are administered under the conditions that are most appropriate and that will produce the greatest benefit.

POLYPHENOLS IN NEUROPROTECTION

Phenolics

Phenolics are ubiquitously found across the plant kingdom, with ~10,000 structures identified to date. Phenolics range from simple low-molecular weight compounds, such as the simple phenylpropanoids, coumarins, and benzoic acid derivatives, to more complex structures such as flavanoids, stilbenes, and tannins. Of these, the flavonoids represent the largest, most diverse group, encompassing some 6000 compounds, all of which share a common underlying structure of two 6-carbon rings, with a 3-carbon bridge, which usually forms a 3rd ring. Flavanoids can then be subdivided according to modifications of this basic skeleton into chalcones, flavones, flavonols, flavanones, isoflavones, flavan-3-ols, and anthocyanins [190].

A wide range of phenolic compounds in the CNS function, directly interact with neurotransmitter systems. As an example, in animal models, a diverse range of individual and combined flavonoids that occur in traditional medicinal extracts exert sedative/ anxiolytic effects via direct binding to GABAA receptors [191-192], cognitive enhancement via antagonistic GABAA receptor binding and resultant cholinergic upregulation [193], and antidepressant effects via monoamine oxidase inhibition and resultant increases in levels of 5-HT, DA, and noradrenaline in select brain areas [194]. In mammals and other vertebrates, phytoestrogens modulate hormonal systems, and therefore brain function, via a variety of mechanisms [195].

Polyphenols

Polyphenols are found in most plant-derived foods and beverages. There are over 8000 polyphenolic structures identified in plants. Polyphenols add to the sensory and nutritional qualities of plant foods. Polyphenols are often involved in the plant's defensive response against different types of stress such as ultraviolet radiation, pathogens, and physical damage. Because plants usually produce these polyphenols as a defensive mechanism, environmental conditions such as soil type, sun exposure, and rainfall along with other factors such as genetics factors, germination, degree of ripeness, processing and storage, and species variety can have effect on the polyphenol concentration. All polyphenols contain an aromatic ring

with one or more hydroxyl group. Most also have at least one sugar residues (glycosides) attached to the hydroxyl groups. They are classified into different groups depending on the number of phenol rings and chemical groups bound to the rings [196-198].

Polyphenols are a group of naturally occurring phytochemicals which are present in high amounts in fruits, vegetables, and natural products and are characterised by the presence of multiple hydroxyl groups on aromatic rings. These compounds are divided into two main categories: the flavonoids and nonflavonoids, based on the number of phenol rings and the way in which these rings interact (Figure 6).

Polyphenols contain a wide range of molecule sizes. Polyphenols, such as phenolic acids, are simple compounds, whereas the tannins are highly polymerized molecules. Flavonoids make up most of the polyphenols and they form the most important single group of polyphenols [196]. Table 1 summarizes the main classes of polyphenols, some representative phenolics in the groups, and their dietary sources. Polyphenols are usually recognized for their antioxidant capabilities. Phenolic antioxidants have been shown to inhibit the oxidation of lipids and other molecules and protect against free radicals [196, 199]. Polyphenols can react with radicals to form polyphenol radicals. The polyphenol radical is more stable and less reactive because of the ability of the phenol group to absorb extra electrons. Most polyphenols are conjugated by methylation, sulfation, or glucuronidation during metabolism. The antioxidant capability could be determined by the type of conjugate and its location on the polyphenol structure. This might be why certain polyphenols are better at scavenging superoxides, whereas others can scavenge the highly reactive oxygen-derived radical peroxynitrite. Their antioxidant capacity may also correlate with their ability to chelate metals. Specific polyphenols can chelate iron and possibly prevent the formation of free radicals by iron [200-203].

Table 1. Major Subclasses of polyphenols, Compounds, and Food Sources

Polyphenol Group	Name of Compound	Sources of the Polyphenol compounds
Flavonoids		
Flavonols	Quercetin, myricetin, kaempferol	Onions, apples, kale, red wine, green and black tea, broccoli, berries
Flavanones	Hesperetin, naringenin, eriodictyol	Citrus fruit, tomatoes, mint
Flavanols (Proanthocyanidins and catechins)	Epicatechin, epigallocatechin, epicatechin 3-gallate, epigallocatechin 3-gallate	Apricots, green and black tea, red wine, chocolate
Anthocyanins	Cyanidin, pelargonidin, malvidin	Strawberries, other berries, grapes, wine, tea, eggplant, cabbage
Isoflavonoids (phytoestrogens)	Genistein, daidzein, glycitein	Lentils, chickpeas, alfalfa, clover, flaxseed, soybeans
Flavones	Apigenin, luteolin, diosmetin, tangeretin, xanthetin, xanthosetin, wogonin	Parsley, celery, skin of citrus fruit
Phenolic Acids		
Benzoic acid derivative	Galllic acid, vanillic, syringic, hydroxybenzoic	Tea, strawberries, raspberries, blackberries, black radish, onions
Cinnamic acid derivative	p-Coumaric, caffeic, ferulic, sinapic acids, vanillin, syringaldehyde, p-hydroxybenzaldehyde	Blueberries, kiwis, plums, cherries, apples, cereal grains, coffee
Lignan	Secoisolariciresinol	Linseed, lentils, cereals, garlic, asparagus, carrots, pears, prunes
Stilbene	Resveratrol	Grapes, red wine
Saponin	Ginsenoside	Ginseng root
Other polyphenols	Curcumin	Turmeric

Polyphenols have been shown to have several other actions in addition to their antioxidant ability. Evidence show that they can inhibit the activities of several enzymes, including lipoxygenase, cyclo-oxygenase, xanthine oxidase, phospholipase A2, ATPases, aldole reductase, phosphodiesterases, topoisomerase I and II, protein kinase C, phosphoinositide 3-kinase, Akt/PKB, (protein kinase B) and mitogen-activated protein (MAPKs) kinases (MAPs) [200, 204-205]. Some polyphenols have weak estrogenic properties and others can inhibit the enzymes involved in estrogen metabolism, aromatase, and 17 β -hydroxysteroid oxidoreductase [205]. The reduction of several diseases has been linked to polyphenols. Cardioprotection and a reduction in certain types of cancer have correlated with consumption of phenolic antioxidants [196, 205]. There is also evidence for polyphenols to be antiallergic, antiviral, antibiotic, antidiarrheal, antiulcer, and anti-inflammatory agents. Polyphenols have been used to treat hypertension, vascular fragility, allergies, and hypercholesterolemia [196, 198-199]. Polyphenols have also been implicated in the prevention of neurodegenerative diseases.

Polyphenols protect neurons against oxidative stress thought to be one of the main causes of neurodegenerative diseases. Even a 10-fold higher concentration of ascorbate did not protect neurons similar to polyphenols [199]. Polyphenols attenuate ischemia-reperfusion injury by interfering with inducible nitric oxide synthase activity, inhibiting lipid peroxidation, decreasing the number of immobilized leukocytes during reperfusion, and reducing complement activation which results in a diminished inflammatory response [200]. Most importantly, in addition to their antioxidant actions, they also influence neuroprotective and neurorestorative signal transduction mechanisms [203]. Epidemiological studies show an inverse relationship between stroke and polyphenol consumption [197]. The dietary intake of polyphenols varies greatly among different societies. Isoflavone intake as a result of soy consumption ranges from 20 to 240 mg for Asians and from 1 to 9 mg in the United States and Western populations [198, 205].

The evidence presented in this section suggests the potential of polyphenols in both preventive and therapeutic usages for cerebral ischemia/reperfusion injuries. Furthermore, no toxic or other adverse side effects were reported with the dietary use of high concentration of polyphenols, although regulated clinical trials have not been performed. In addition, their bioavailability, absorption, and metabolism also require more studies, especially in humans. It would be particularly important to compare individual polyphenols with extracts of fruits, beverages, and vegetables in preclinical and clinical projects and to further investigate possible mechanisms of their effects. Numerous studies have indicated that compounds in an extract can act synergistically so it would be advantageous to use multiple polyphenols in the treatment of stroke. In particular, when stroke symptoms appear, a substantial damage has already taken place in the brain. Therefore, treatments have to start as early as possible in order to reduce further neurodegeneration and promote regeneration. However, the preventive use of plant products will be likely the most effective strategy for the treatments of stroke and other age-related neurodegenerative disorders.

Phenolics, and flavanoids in particular, are ubiquitous in plants and therefore represent an important component of a normal human diet. Epidemiological studies have suggested associations between consumption of phenolic-rich foods or beverages and various diseases, such as stroke, cardiovascular disease, and cancer [206] and neurologic disorders such as dementia/AD [207-208]. Naturally, multiple phenolic compounds coexist in foods. Many investigations utilizing animal models have demonstrated, for instance, that berry extracts

with high levels of anthocyanins or other polyphenols can reverse brain insult- and age-related cognitive decrements in rodents and that the actives can cross the blood brain barrier [209]. Similarly, in healthy humans, complex mixtures of cocoa-flavanols have been shown to increase peripheral vaso-dilation and cerebral blood flow during task performance, as indexed by functional MRI [210], and improve performance on cognitively demanding tasks [211]. However, the majority of the research in this area is concentrated on the effects of single molecules and the following includes a review of evidence surrounding the 3 most promising single molecule candidates. The chemical structure of curcumin, EGCG and resveratrol are shown in Figure 7.

Curcumin. Curcumin, a curcuminoid polyphenol responsible for the bright yellow color of the Indian spice turmeric (*Curcuma longa* L.), has been utilized for centuries within the Ayurvedic system of medicine for the treatment of a whole host of ailments, including inflammation [212]. Curcumin exerts varied and wide-ranging effects on molecular targets [213]. These include transcription factors such as NF- κ B, a master regulator of the antioxidant response; the protein kinases, which are involved with the majority of cellular pathways, especially those involved with signal transduction; enzymes such as heme oxygenase 1, a stress response protein whose expression is upregulated after curcumin consumption and associated with neuroprotection [214]; invasion and angiogenesis biomarkers such as matrix metalloproteinase 9, which are associated, among numerous other activities, with tissue repair; and inflammatory mediators such as NF- κ B and cytokines such as TNF α and IL-1 and IL-6 [215].

In animals, some of the physiological effects attributed to curcumin include activity against a range of neurologic diseases in animal models, including AD, multiple sclerosis, Parkinson's disease, age-associated neurodegeneration, schizophrenia and depression [216-221].

EGCG. A number of the catechin polyphenols that are abundant in tea (*Camellia sinensis* L.) are reputed to have pharmacologically active properties. The 4 main tea flavanols are: (-)-epigallocatechin, (-)-epicatechin, (-)-epicatechin-3-gallate, and EGCG, with EGCG generally thought to be the main and active component in green tea. The potentially neuroprotective effects of EGCG include direct effects seen in vitro in metal chelation [222], as an anti-inflammatory agent [223], and in the reduction of amyloid- β and amelioration of amyloid- β induced neurotoxicity [224-225], with these neuroprotectant properties being in part mediated via the activation of cell survival genes and modulation of protein-kinase c signaling [222]. EGCG has also been shown to facilitate cholinergic transmission [226], enhance neurite outgrowth [227], and modulate cerebral blood flow parameters in healthy humans. In vivo evidence from animal models suggests neuroprotective properties in the face of AD [228-230] and Parkinson's disease [231] and following ischemia/reperfusion injury [232-233]. Longterm administration of green tea catechins (63% EGCG) has also been shown to improve cognitive performance and increase antioxidant capacity in normal rats [234] and rats infused with amyloid- β [235]. EGCG was also found to significantly increase the lifespan of *Candida elegans*, although, interestingly, this was observed only during situations of increased heat and oxidative stress [236].

This might suggest that the life-extending (and perhaps other) effects of EGCG are due to antioxidant actions and an upregulation of stress resistance-related proteins such as heme oxygenase 1. Indeed, pretreatment of cells with EGCG is associated with an increase in levels of heme oxygenase 1 [237]. Despite the relatively small number of investigations into the

neuroprotective properties of EGCG in humans, epidemiological evidence reports that higher consumption of tea/green tea is associated with a reduced risk of neurodegenerative disorders [238] and a lower prevalence of cognitive impairment. Future research should therefore consider both acutely and chronically supplementing green tea catechins to young, healthy participants as well as to those with cognitive senescence.

Figure 7. Structures of phenolic compounds like Curcumin, Resveratrol and EEG.

Resveratrol. The phytoalexin resveratrol (3, 4, 5 trihydroxystilbene) is produced within a range of edible plants in response to tissue damage and environmental stressors such as fungal and viral attack [239-240]. Consumption of resveratrol is associated with numerous protective health benefits in mammals, including increased longevity [241], antiinflammatory [242] and antiviral properties [243], and protection against cancer and tumorigenesis [244], cardiovascular disease [245], and atherosclerosis [246]. With regards to these latter 2 effects, resveratrol has been associated with the French paradox, whereby the consumption of red wine in some cultures has been suggested to contribute to a relatively low incidence of coronary heart disease despite a diet high in saturated fats [247-248]. Potential neuroprotective mechanisms of action include improving blood flow and perfusion [249] and the promotion of antioxidant defenses [250], which in vivo are likely to be as a result of resveratrol bolstering the bodies' own endogenous antioxidant defenses via upregulation of a host of antioxidant enzymes [251]. This may be partly a consequence of activation of the Nrf2 transcription factor, which plays a central role in the regulation of cellular redox status [252] and modulation of the protein kinases, which were observed to be involved with neuroprotection against amyloid- β -induced toxicity [253] in vitro [254] and in vivo, specifically in the hippocampus [255]. In vivo, oral administration has also been shown to diminish amyloid- β plaque formation in a region-specific manner in a transgenic mouse model [256].

Protective Role of Polyphenols in Neuronal Ischemic Injury

A significant interest on the protective effects of polyphenols has principally been because of their antioxidant properties. Phenolic antioxidants have been shown to inhibit the oxidation of lipids and other molecules and protect against free radicals [257]. Oxidative stress is a key event in the pathogenesis of cerebral ischemia. Overproduction of ROS during ischemia and/or ischemia/reperfusion can damage lipids, proteins, and nucleic acids, thereby inducing apoptosis or necrosis. Increasing evidence supports the hypothesis that plant polyphenols provide protection against neurodegenerative changes associated with cerebral ischemia [258]. Whether regional differences exist in the brain in the protective effects of polyphenols in ischemic injury is not clear. Most studies have reported the protective effects of polyphenols in the hippocampal and cerebral cortex regions in ischemia. Inanami et al. [259] observed a dose-dependent protection against hippocampal neuronal death in ischemia in gerbils after ad libitum oral administration of catechin in the drinking water for 2 weeks. Epigallocatechin-3-gallate (EGCG) also protected the hippocampal region in gerbils after transient global ischemia [260] and neuronal damage in a rat model of transient focal cerebral ischemia [261]. EGCG (50 mg/kg; intraperitoneal) was effective even when it was administered 3 hr after the ischemic insult in gerbils [262]. Hong et al. used green tea extract in the drinking water ad libitum for 3 weeks before ischemia in gerbils. This treatment reduced the infarct volume, the number of apoptotic cells, and lipid peroxidation, and inhibited the ischemia-induced hyperactivity [263]. In another focal ischemia model using middle cerebral artery occlusion (MCAO) in rats, the protective effects of resveratrol were shown with pretreatment for 21 days (20 mg/kg intraperitoneally per day). The treatment reduced the infarct volume, prevented motor impairment, and inhibited lipid peroxidation [264]. A single dose of resveratrol (20 mg/kg) given orally 1 hr before permanent middle cerebral artery ligation in mice did not protect against ischemic damage. However, when given daily for 3 days before ischemia, resveratrol significantly reduced the infarct size. In another study, effects of resveratrol on transient global cerebral ischemic injury were examined in gerbils [265]. Resveratrol (30 mg/kg given intraperitoneally per day) was injected either during or shortly after common carotid artery ligation and 24 hr later. Resveratrol significantly decreased neuronal death in the hippocampus and also inhibited glial cell activation. Nanocapsule encapsulated quercetin treatment resulted in significant protection to endogenous antioxidant enzymes against ischemia induced oxidative damage in neuronal cells of young and old rats [266]. Not many studies have reported the effects of polyphenols in the striatum except that by Shukla et al. [267] who saw a significant inhibition in lipid peroxidation and an increase in superoxide dismutase (SOD) activity in corpus striatum in rats pre-treated with curcumin prior to MCAO.

Some studies have examined the protective effects of polyphenols in the striatum but not in ischemic injury. For instance, GTE and EGCG were effective in preventing the depletion in striatal dopamine and tyrosine hydroxylase protein levels in a mouse model of Parkinson's disease [268]. It appears from these studies that protective effects of polyphenols would potentially be observed in the striatal region if assessed in ischemic injury. As mentioned above, cerebral cortex is another region where ischemic injury has been observed. Shukla et al. [267] reported an antioxidant effect of curcumin in the cortex of rats subjected to MCAO. Red wine polyphenol compounds also protected against oxidative stress in rats following MCAO/reperfusion [269]. Similarly, resveratrol significantly attenuated neuronal death in and decreased the generation of ROS, lipid peroxidation and nitric oxide (NO) content in the

cortex of rats subjected to transient global ischemia [270]. 2,3,5,4'-tetrahydroxystilbene- 2-O-beta-D-glucoside (TSG), an active component of the rhizome extract from *Polygonum multiflorum*, significantly reduced infarct volume in the cortex following MCAO [271]. Taken together, these studies indicate that polyphenols either exert or have the potential to exert neuroprotective effects in various regions in the brain that are vulnerable to ischemic injury. While the precise dose required to achieve a neuroprotective effect in cerebral ischemia is not clear and may vary with individual polyphenols,

Sutherland et al. [261] have reviewed the effects of green tea catechins including the safety and efficacy of such catechins. One mechanism underlying the neuroprotective effect of polyphenols is possibly through its effects on reducing the levels of apoptotic markers. Pomegranate polyphenols and resveratrol protect neonatal mouse brain from ischemic injury by reducing caspase-3 and calpain activation [272]. In neonatal rats, amentoflavone blocked the activation of caspase-3 and the proteolytic cleavage of its substrates following hypoxic-ischemic injury [273]. Pomegranate juice also diminished caspase-3 activation in the hippocampus and cortex of the neonatal brain against a hypoxic-ischemic insult through supplementation of the maternal diet with pomegranate juice [274]. Mangiferin and morin, two antioxidant polyphenols, are neuroprotective in both in vitro and in vivo models of ischemia possibly by reducing Ca^{2+} influx and decreasing caspase-3 [275]. A subsequent in vitro study by Campos-Esparza et al. [276] demonstrated that mangiferin and morin reduced the formation of ROS and restored the mitochondrial membrane potential following excitotoxic stress, which is a major component of ischemic injury. Further, these polyphenols also reduced the glutamate-induced activation of calpains, normalized the level of cytosolic Bax and inhibited the release of AIF from mitochondria. These actions of mangiferin and morin could well be part of their profile in an in vivo model of ischemic injury. EGCG, a green tea polyphenol, reduced up-regulation of MMP-9 activity and neuronal damage following transient focal cerebral ischemia in C57BL/6 mice [277]. MMP-9 downregulation by resveratrol was also observed in an in vitro model of neuronal ischemic injury [278]. 5,7,3',4',5'-pentahydroxy dihydroflavanol-3-O-(2"-Ogalloyl)-beta-d-glucopyranoside (AP1), a polyphenolic compound isolated from *Anogeissus pendula* Edgew (an arid forest tree), was effective in reducing apoptotic cells in rat brain following transient focal cerebral ischemia [279]. The effect of TSG in protecting rat brain from MCAO is by increasing the anti-apoptotic Bcl-2 proteins.

Curcumin, a potent polyphenol antioxidant enriched in turmeric, reduced cytochrome c release and subsequent caspase-3 activation following global cerebral ischemia in Mongolian gerbils [280]. While the aforementioned studies have demonstrated a decrease in caspase-3 levels in the presence of polyphenols, it is unclear whether polyphenols act directly on caspase-3 or whether they act on upstream caspases that are precursors to caspase-3. Alternatively, such polyphenols could also be activating inhibitor of apoptosis (IAP) which would then inhibit caspase-3 activation. In addition, effects of polyphenols may also involve protecting mitochondrial dysfunction in ischemic injury as seen in vitro [281]. Preventing the decline in mitochondrial membrane potential following ischemic injury may subsequently confer protection against apoptotic cell death. In addition, resveratrol can induce neuroprotection by increasing mitochondrial ATP synthesis efficiency in rat brain following ischemia [282]. While these studies highlight the potential neuroprotective mechanisms by which polyphenols attenuate cell death in ischemia, their antioxidant and anti-inflammatory

effects may also contribute to their ability to reduce cell swelling and/or brain edema which can be deleterious to neuronal and glial functioning.

Role of Polyphenols in Attenuating Oxidative Stress and Mitochondrial Dysfunction in Brain Edema and Cell Swelling

Oxidative stress is a key component of ischemic injury including cell swelling and brain edema and polyphenols, due to their antioxidant properties, would be postulated to attenuate such injury. Reports on the beneficial effects of polyphenols on brain edema in ischemia are scarce. Resveratrol has been reported to reduce brain edema in rats following MCAO [283]. Lee et al. has reported a protective effect of green tea polyphenol EGCG against neuronal damage and brain edema after unilateral cerebral ischemia in gerbils. AP1, a polyphenolic compound, also reduced brain edema in rats after transient focal ischemia [284]. Recently the protective effects of polyphenols from green tea as well as cinnamon on glial swelling in cultures following ischemia-like injury has been reported [285]. Myricetin and quercetin also attenuated cell swelling following oxygen-glucose deprivation in C6 cultures [286]. While in cell culture studies polyphenols reduced cell swelling, it is possible that the reduction in cell swelling was not due to the antioxidant effects of polyphenols.

An increase in intracellular calcium is a key feature of ischemic injury [287]. Further, an increase in $[Ca^{2+}]_i$ can induce cell swelling as demonstrated in lacticidosis-induced glial swelling [288] and in hypo-osmotic swelling in cultured astrocytes [289]. It has been demonstrated that quercetin and myricetin both attenuate OGD-induced increase in $[Ca^{2+}]_i$. Also, such blockade of the rise in $[Ca^{2+}]_i$ by blockers of the L-type calcium channel as well as modulation of $[Ca^{2+}]_i$ through BAPTA, a calcium chelator, reduces cell swelling in C6 glial cultures [290]. Other studies have also shown a decrease in $[Ca^{2+}]_i$ following administration of polyphenols. Quercetin attenuated the H_2O_2 -induced calcium dysregulation in PC12 cells [291]. Quercetin, catechin, and resveratrol also inhibited cardiac voltage gated sodium channel in rat cultured myocytes, but had no effect on the reverse mode NCX, the Na^+ / Ca^{2+} exchanger [292]. Apple condensed tannins inhibit the increase in intracellular free Ca^{2+} concentration in RBL-2H3 cells induced by antigen stimulation [293]. EGCG reduces the glutamate-induced $[Ca^{2+}]_i$ increase by attenuating ionotropic Ca^{2+} influx in PC12 cells [294]. Nevertheless, these studies indicate that polyphenols have the potential to modulate calcium channels that are involved in cell volume regulation, but their role in attenuating glial swelling/cytotoxic edema in ischemia needs to be further elucidated.

Mitochondrial dysfunction is an important characteristic of ischemia. The mitochondrial permeability transition (mPT) has been implicated as one mechanism, or at least part of the mechanistic pathway, for cell swelling in cultured astrocytes following ammonia toxicity or TBI as well as in brain sections in ischemia [295]. Despite these studies, the role of the mPT in cell swelling is not clear. Recently it has been demonstrated that the attenuation of cell swelling and the prevention of the decline in mitochondrial inner membrane potential ($\Delta\Psi_m$) by immunosuppressants, cyclosporin A (CsA), but not FK506, are consistent with the role of the mPT mediating such events. Similar to CsA, CPE, and green tea polyphenols, also significantly prevented OGD-induced cell swelling and the decline in $\Delta\Psi_m$ in C6 glioma indicating that one mechanism by which CPE and GTE exert their protective effects is possibly by blocking the mPT. Interestingly, quercetin significantly attenuated cell swelling in C6 glial cells following OGD but did not block the dissipation of the $\Delta\Psi_m$ [290] indicating that other factors, besides the mPT, mediate the development of cell swelling in ischemic

injury. It is also possible that preventing the induction of the mPT may be sufficient in some cases but may not be always necessary.

An increase in inflammatory markers has been associated with brain edema [296] and could potentially cause damage to the BBB [297]. A disruption of the BBB is observed in vasogenic brain edema. A key characteristic of polyphenols is their anti-inflammatory property [298] and anti-inflammatory effects of polyphenols have been reported in cerebral ischemia [299]. Inflammatory molecules can damage mitochondrial function. For instance, exposure of rat astrocyte cultures to interferon γ , in the presence or absence of LPS, can increase NO production which can subsequently damage the mitochondrial respiratory chain complex function. Studies that investigated the role of polyphenols on BBB function in ischemia are scarce except that reported by Zhang et al. [300] which examined the effects of green tea polyphenols on BBB permeability following MCAO in rats. They report a decrease in BBB permeability in the ischemic region in the presence of green tea and a concomitant decrease in levels of caveolin-1, a protein involved in BBB functioning and permeability. Wang et al. and Lee et al. report a reduction in water content in the brains of animals following ischemia with resveratrol and EGCG respectively, but it is not clear if the edema that was measured was of the vasogenic or cytotoxic type. Likewise AP1, a polyphenolic compound, also reduced brain edema in rats following MCAO but the type of edema assessed is not clear. A reduction in BBB damage and water content in the brain following cerebral ischemia in rats was reported with curcumin [301]. Curcumin also decreased brain edema in rats following MCAO [302] but as with some other studies the type of edema examined is not clear. In a rat thromboembolic stroke model, curcumin reduced brain edema [303] most likely of vasogenic type.

In addition, curcumin was reported to significantly lower oxidized proteins and interleukin-1 β , a pro-inflammatory cytokine, elevated in the brains of AD transgenic mice [304]. IL-1 receptor 1 (IL-1R1)-null mice when subjected to hypoxia-ischemia showed reduced cytotoxic and vasogenic edema when compared to wild-type mice [305]. Taken together it is conceivable that curcumin could attenuate vasogenic edema following ischemia. Further, anti-inflammatory properties of polyphenols have been reported in other stresses and this knowledge can be applied to vasogenic edema in ischemia. Polyphenols found in cinnamon also have anti-inflammatory effects in vitro [306]. A reduction in TNF- α , an inflammatory cytokine, has been reported for green tea polyphenols [307] as well as dried plum polyphenols [308] and TNF- α is one agent that increases endothelial permeability in vasogenic edema. Also, increases in intercellular adhesion molecule (ICAM-1) and myeloperoxidases in rodent lung injury are attenuated by green tea polyphenols [309]. In addition, anti-cyclooxygenase 2 effects of resveratrol [310], as well as anti-MMP9 effects of resveratrol [311] and other polyphenols have been demonstrated. The importance of inflammation in vasogenic edema, taken together with the anti-inflammatory effects of polyphenols, indicates that the polyphenols may play a protective role in reducing vasogenic brain edema in ischemia.

Oxidative stress and mitochondrial dysfunction are key features of cerebral ischemia that affect neuronal viability after ischemia. Edema can further aggravate neuronal injury by affecting cerebral perfusion. Currently, there are few remedial agents to effectively reduce neuronal death or brain edema not only in ischemia but also in other neural injuries including traumatic brain injury. The potential for the use of polyphenols in the preventing cell loss or damage and edema in cerebral ischemic injury is tremendous. However, the cellular and

molecular actions of polyphenols involved in neuroprotection have to be elucidated further. Given the large proportion of the population affected by stroke and traumatic brain injury, and with few strategies to effectively attenuate brain edema and associated neural damage, it is important to determine the potential beneficial effects of dietary polyphenols in the prevention and alleviation of such damaging effects.

Role of Polyphenols in Preventing Neuroinflammation

Although neuroinflammation plays a critical role in brain host defence, it also contributes to the underlying neuronal loss in neurodegenerative disorders and to damages associated with cerebral ischemia [312]. Neuroinflammation is “driven” by activated resident glial cells (astrocytes and microglia) which result in invasion of circulating immune cells and the production of proinflammatory cytokines (TNF- α , IL-1 β , and IL-6), nitric oxide (NO), prostaglandin E₂, chemokines, and reactive oxygen species (ROS). Amongst the numerous factors released by activated glial cells, excessive NO• production has been reported to induce neuronal cell death by damaging the mitochondrial electron transport chain function in neurons [313] therefore resulting in neuronal ATP synthesis disruption and in increased generation of ROS [114]. Furthermore, NADPH oxidase activation, an important event in activated microglia-induced neurotoxicity, has also been suggested to mediate both superoxide (O₂•-) production and to release proinflammatory molecules such as TNF- α [314]. NO• produced in microglia or astrocytes may react with O₂•-, produced by NADPH oxidase to generate the neurotoxic peroxynitrite radical (ONOO-) [315]. ONOO- has been observed to inhibit mitochondrial respiration, induce caspase-dependent neuronal apoptosis, and to induce glutamate release resulting in excitotoxicity and neuronal death [316]. Additionally, glial cytokine production may also play a deleterious role in neurodegenerative diseases by binding to specific cell surface receptors expressed in neurons and activating apoptotic pathways.

There has been much interest in the development of new drugs capable of preventing neuroinflammatory-mediated brain injury. Emerging evidence suggests that dietary polyphenols may exert neuroprotective effects by suppressing the activation of microglia, which mediates inflammatory processes in the CNS. Although rather complex, the main anti-inflammatory properties of polyphenols include: (1) an inhibitory role on the release of cytokines, such as IL-1 β and TNF- α , from activated glia; (2) an inhibitory action against iNOS induction and subsequent nitric oxide production in response to glial activation; (3) an ability to inhibit the activation of NADPH oxidase and subsequent ROS generation in activated glia; (4) a capacity to downregulate the activity of proinflammatory transcription factors such as NF- κ B through their influences of a number of glial and neuronal signaling pathways, such as MAPK cascade (discussed in details below) [317-318].

For example, the commonly consumed flavonol quercetin has been reported to inhibit neuroinflammation by attenuating nitric oxide production and iNOS gene expression in microglia [319] and by preventing inflammatory cytokine production, thus preventing neuronal injury [320-321]. However, one of the major physiological metabolites of quercetin, quercetin-3_-sulfate, failed to demonstrate any anti-inflammatory action. Nevertheless, these studies have employed quercetin concentrations (10–50 μ M) much higher than of those found in plasma after ingestion.

Figure 8. Mechanisms underlying the biological effects of polyphenols. Polyphenols and their *in vivo* metabolites activate cellular stressresponse pathways resulting in the upregulation of neuroprotective genes. For example, both PKC and ERK can activate the nuclear factor erythroid 2-related factor 2 (Nrf2). Nrf2 then translocates to the nucleus and binds to the antioxidant response element (ARE) in genes that encode cytoprotective proteins such as antioxidant enzymes (AOE) and phase 2 (Ph2) enzymes. The transcription factor cAMP-responseelement-binding protein (CREB) is also activated by ERK, which induces the expression of brain-derived neurotrophic factor (BDNF), a mediator of neurohormesis. In addition, polyphenols can also regulate the transcription factor NF- κ B, which can mediate adaptive cellular stress responses by reducing the expression of inflammatory cytokines. Activated SIRT1 may also inhibit NF- κ B and so can reduce the cellular stress response. Another important pathway activated bymetabolic and oxidative stress involves transcription factors of the forkhead (FoxO) family, which modulate genes that encode antioxidant enzymes and other stress-response proteins.

In contrast to this, epicatechin and catechin (10–300 nM) were observed to inhibit TNF- α release but not iNOS expression or nitric oxide production in primary glial cells [322] suggesting that flavanols at physiologically relevant concentrations may hold the potential to exert anti-inflammatory effects in the central nervous system. Polyphenols present in blueberry have also been reported to inhibit NO $\cdot$, IL-1 β and TNF- α production in activatedmicroglia cells [323], and the flavanone naringenin was observed to be highly effective in reducing LPS/IFN- γ -induced glial cell activation [322].

Dietary polyphenols are also potent inhibitors of NADPH oxidase activity *in vitro*. A study comparing 45 polyphenolic compounds indicated that whilst both the flavanols (+)-catechin and (–)-epicatechin failed to inhibit NADPH oxidase, their relevant methylated metabolites exhibited strong NADPH oxidase inhibition through an apocynin-like mechanism [324]. Interestingly, other apocynin-like phenolic compounds, such as, ferulic acid, homovanillin alcohol, caffeic acid, tyrosol, and vanillic acid were also observed to inhibit NADPH oxidase activity, therefore indicating that smaller polyphenols, more structurally related to some colonic metabolites, may also serve as novel therapeutic agents in neuroinflammation (Figure 8).

There is also data which shows encouraging positive effects of polyphenols in animal and *in vitro* models relevant to multiple sclerosis (MS), a chronic debilitating disease which is characterised by demyelination, progressive irreversible axonal damage and inflammation [325]. For example, EGCG delivered orally reduces symptom severity in the autoimmune encephalomyelitis model of relapsing-remitting MS by reducing inflammation and increasing neuroprotection [326]. Quercetin has also been reported to be effective in the Experimental Autoimmune Encephalomyelitis (EAE) mouse model, and reduces T-cell proliferation *in vitro* at concentrations exceeding 10 μ M [327]. Micromolar concentrations of luteolin, apigenin, fisetin, and quercetin (but not morin or hesperetin) were reported to suppress the production of the cytokine interferon-gamma (IFN γ) from lymph-node-derived T cells but, paradoxically, worsen clinical severity in the EAE model. More recently, resveratrol protection against EAE was associated with rises in IL-17/IL-10 and with repressed macrophage IL-6 and IL-12/23 p40 expression [328]. Thus, the studies to date show promising proof of concept of beneficial effects of polyphenols in suppressing immune and inflammatory responses in models of MS.

Neuroprotection by Polyphenols in Hypoxic-Ischemic Injury in Neonates

Dietary supplementation with foods rich in polyphenols—pomegranates, blueberries, green tea, and apple juice—has been shown to provide neuroprotection in animal models of focal brain ischemia, of periventricular white matter injury, and of Alzheimer's disease [329-332]. Polyphenols have been found to possess antioxidant properties as well as to have effects on gene expression [333]. Specifically, one polyphenol, resveratrol, has been shown to increase activity of members of the sirtuin gene class, blunting p53 action and blocking apoptosis [334-335]. Recent studies indicate that among foods that contain polyphenols, juice extracted from the pomegranate has the highest concentration of measurable polyphenols [336-337]. The pharmacologic actions of pomegranate juice include antiatherosclerotic, antibacterial, and antiproliferative properties [338]. Recently it has been found that when the polyphenol rich pomegranate juice is consumed by the dam polyphenols from the juice are present in the pup and protected the pup against H-I brain injury [274]. Other studies have shown that the polyphenols caffeic acid phenylethyl ester and amentoflavone are also protective against neonatal H-I brain injury [273]. To test the hypothesis that it is the polyphenols of pomegranate juice that are responsible for neuroprotection, the effect of pomegranate polyphenol extract (PPE) in the neonatal H-I mouse model was tested and it was observed that supplementation of PPE to the drinking water of pregnant and nursing dams resulted in significantly decreased H-I induced caspase-3 activation. This suggests that it is the polyphenols of the pomegranate juice that are responsible for the neuroprotection.

Resveratrol the naturally occurring compound has been found to be neuroprotective in adult ischemia in rats when administered before the injury, but to our knowledge resveratrol has never been tested in neonatal H-I [339-341]. By examining a variety of different concentrations at several different time points it was found that IP injection of resveratrol leads to decreased caspase-3 activation in the P7 mouse in a concentration and time dependent manner. At doses of 200 μ g/kg or greater, resveratrol leads to decreased caspase-3 activation but only when resveratrol is injected prior to the injury. In addition to decreasing the caspase-3 activation resveratrol also decreases the calpain activation following neonatal

H-I, suggesting that it works as a generally neuroprotective agent and not just on the apoptotic pathway.

In addition to finding that resveratrol is protective in the neonatal mouse it was also demonstrated that resveratrol protects the neonatal rat against H-I induced caspase-3 activation. Although the injury paradigm is similar in rats and mice there are several neuroprotective agents that have been found to work only in one species. Since resveratrol has been found to protect against stroke in neonatal rats and mice as well as in adults, it could potentially be considered for further investigations in humans. Interestingly, the resveratrol was not found to be protective in the rat when given after the injury. Since the apoptotic cell death in the rat starts much later in the rat than in the mouse, and several drugs have been shown to be protective in the rat when given after the insult, we thought that resveratrol might follow the same pattern. The fact that resveratrol does not protect when given after the injury suggests that it is acting through proximal mechanisms in the cell death pathway initiated by H-I. One pathway that may be involved in the effects of polyphenols is via activation of the sirtuins such as SIRT1.

Polyphenols such as resveratrol may have beneficial effects on health via their antioxidant properties, suppression of inflammatory pathways, or other pathways such as activation of the sirtuin pathway [342]. Included in the sirtuin family is SIRT1, a human protein deacetylase that promotes cell survival by mechanisms such as negatively regulating the p53 tumor suppressor [343], deacetylating the transcription factor FOXO3 [344], repressing PPAR γ signaling [345] and modulation of NF- κ B dependent transcription [346]. Modulation of these pathways may provide a means to protect the developing brain against neonatal H-I induced brain damage. Recent studies show that polyphenols, including resveratrol, increase cell survival via activation of SIRT1 [41]. Parker et al. found that increased *sir2* gene dosage or treatment with resveratrol in *C. elegans* blocked neuronal dysfunction and cell death induced by polyglutamine expansion. Suggesting that resveratrol may act through a similar pathway in mammals, resveratrol protected mammalian neuronal cell lines from mutant huntingtin-induced cell death and this effect was inhibited by sirtuin inhibitors [347]. There is also evidence that resveratrol can block axonal degeneration via SIRT1 in the mammalian peripheral nervous system [348]. While increasing evidence suggests that resveratrol and other polyphenols are neuroprotective, whether their protective actions in the CNS *in vivo* are via SIRT1 has not been directly assessed. Determining the mechanism of protection of resveratrol, pomegranate polyphenols, and other polyphenols may lead to novel insights into both pathogenesis and treatment of neonatal H-I brain injury.

Resveratrol, a natural stilbene present at relatively high concentrations in grape skin and seeds and red wine, is known for its purported antioxidant activity in the vascular and nervous systems. In contrast to its direct antioxidant role within the central nervous system, recent research supports a protective mechanism through increasing endogenous cellular antioxidant defenses, which triggers a cascade of parallel neuroprotective pathways. A growing body of *in vitro* and *in vivo* evidence indicates that resveratrol acts through multiple pathways and reduces ischemic damage in vital organs, such as the heart and the brain, in various rodent models. Most of the protective biological actions of resveratrol have been associated with its antioxidative, anti-inflammatory, and antiapoptotic properties and other indirect pathways see figure 9.

Figure 9. Potential targets associated with anti-stroke activity of resveratrol.

Resveratrol exhibits therapeutic response against stroke by preventing brain infarct, edema, mitochondrial dysfunction and cognitive and motor impairment. Furthermore, it diminishes nitrosative, oxidative, and DNA damage, which leads to preclusion of apoptosis and neuroinflammation

Summary

The neuroprotective actions of dietary polyphenols involve a number of effects within the brain, including a potential to protect neurons against injury induced by neurotoxins, an ability to suppress neuroinflammation, and the potential to promote memory, learning, and cognitive function. While many of the mechanisms underpinning their beneficial effects remain to be elucidated, it has become clear that they in part involve decreases in oxidative/inflammatory stress signaling increases in protective signaling, and may also involve hormetic effects to protect neurons against oxidative and inflammatory stressors. Most of the dietary polyphenols that have been shown to be protective against age-related disease are all chemically reactive and nearly all are electrophilic.

Such chemical features renders these molecules capable of influencing the redox potential of their target cells and to modulate series of transcriptions factors that result in the activation of phase I and phase II metabolism genes. Nonetheless, much of the data obtained on their bioactivity derived from short-term basis *in vitro* or *in vivo* studies where the dose used was not of nutritional relevance. Although at the moment, the balance of evidence that does suggest that polyphenol effects contribute to the benefits of a high intake of fruits and vegetables, the extent of their contribution *in vivo* and at physiological relevant concentrations remains uncertain. More work needs to be done to prove whether this class of compounds is most likely to result in health benefits and to determine their beneficial effects in slowly developing neurodegenerative disorders. In view of their multiple biological

activities, the consumption of polyphenol-rich foods throughout life holds a potential to limit neurodegeneration and to prevent or reverse age-dependent deteriorations in cognitive performance. However, the therapeutic and pharmacological potential of these natural compounds still remains to be translated in humans in clinical conditions. Moreover, efficacy in RCT is also needed to support the relatively consistent epidemiological and mechanistic evidence. Despite this lack of efficacy data and the uncertainty of their effects *in vivo*, investigations into the absorption and metabolism of various polyphenols in humans indicate that there are common pathways for the metabolism of the majority of polyphenols, notably via their bacterial metabolism in the large intestine. Consequently, research on developing dietary polyphenols for applications in neurodegenerative disorders should prioritise investigations of smaller polar polyphenols for brain bioavailability and bioactivity. The challenge ahead therefore is to proceed cautiously until rigorous randomized controlled clinical trials have been undertaken to determine empirically whether polyphenols and/or their metabolites have efficacy in individuals affected by dementia and other neurodegenerative conditions.

In general, the literature on the efficacy of the herbal extracts and phytochemicals reviewed here in terms of improving aspects of human brain function is somewhat equivocal. Research into the 2 alkaloids, caffeine and nicotine, is confounded by withdrawal effects and most of the remaining treatments have failed to progress beyond relatively small scale human studies. Indeed, in the case of the single molecule polyphenols (curcumin, resveratrol, EGCG), their huge and exponentially expanding literatures are singularly lacking in reports of relevant human intervention trials. Of the 3 treatments that have progressed to larger scale controlled trials and eventual meta-analyses, both GB and valerian are be devilled by methodological inconsistencies and inadequacies that make conclusions difficult to draw, with only St. John's Wort consistently demonstrating efficacy.

One consistent feature across the phytochemical groups is a gradation seen in terms of ecological roles and toxicity. Although something of a generalization, it is possible to characterize alkaloids as occupying the toxic extreme in terms of their deterrent effects in insects and other herbivores, with terpenes inhabiting the middle ground with a more mixed toxicity profile and a wider range of deterrent/ attractant/protective ecological roles. Phenolics then occupy the more benign end of the spectrum, exerting many internal protective roles and managing nontoxic interactions with herbivores and symbiotes. The same gradation could be suggested for the factors underlying the CNS effects in humans. Many of the behavioral effects of low doses of alkaloids are evidently the consequence of modulation of the same CNS mechanisms in both insects and humans and they elicit similar behavioral profiles given the comparative complexity of the taxa (Table 1). Although little research has addressed the effects of terpenes and phenolic compounds on insect behavior, it is possible to speculate that the CNS effects of terpenoids may be balanced between those predicated on similarities between human and invertebrate herbivores, e.g., the cholinesterase inhibitory and direct cholinergic and GABAergic receptor binding properties of many terpenes, and also the similarities between human and plant molecular physiology.

The phenolic compounds, particularly those like flavonoids that are ubiquitously consumed in plant-based foods, may then owe the balance of their CNS effects to the latter (but with notable exceptions in terms of hormonal effects and GABAergic effects). As well as the natural compatibility of molecules created by conserved stress signaling pathways common to both plants and humans, it is interesting to note that the induced

antibacterial/fungal and viral effects of curcumin, EGCG, and resveratrol within the plant may be mirrored by a similar protection conferred after exposure to similar pathogens in human cells and animal models. Although an exact concurrence between the mechanisms of action across the taxa has not yet been established, Friedman has demonstrated that, *in vitro*, the antibacterial, antitoxin, antiviral, and antifungal properties of tea flavonoids were similar against all of the food-borne pathogens reviewed.

These mechanisms ostensibly involved either binding to the invader and inactivating it or perturbing the membrane structure of the pathogen and causing leakage, with both resulting in preventing or limiting the deleterious effects of the bacteria, toxin, or virus. With phenolic compounds in particular it is also interesting to note that humans are likely to have lost the ability to synthesize vitamins, which include several terpenoids and methylated phenols, because the ubiquity of these micronutrients in our diet made it more advantageous in evolutionary terms to sequester them from food rather than synthesize them *de novo*. The same argument has been made for all dietary antioxidants, including many nonvitamin phytochemicals, and this proposition could be extended to include the nonantioxidant properties of groups of phytochemicals that occurred as part of our natural ancestral diet. This would largely accommodate the phenolic compounds, and flavonoids in particular, that are ubiquitous in plant foods. It may be relevant that most phenolic compounds have low parent molecule bioavailability but still exhibit *in vivo* bioactive effects. The rapid process of metabolism that takes place in the body could be viewed as the body processing the molecules into, for instance, glucuronidated and sulfated metabolites to more effectively transport and utilize them, in much the same way that vitamins are processed into their active metabolites and derivatives following consumption.

The gradation in toxicity and ecological/CNS functions is also seen in the comparative levels of research attention paid to the chemical groups. The alkaloid group has benefitted from intense research for over 200 yrs and has provided a multitude of medicinal compounds with CNS activity. Interest in terpenes, on the other hand, has really only escalated in the last 25 yrs, during which time many advances have been made in terms of characterizing the constituents and activities of complex plant extracts that often have low toxicity, high bioavailability, and a multitude of potentially relevant physiological effects. Similarly, research into the health effects of phenolic compounds has only reached any considerable level within only the last 15 yrs. In the case of alkaloids, they have proven particularly amenable to research and drug discovery because of their comparatively straightforward, single molecule modes of action. Evidence suggests that extracts with largely terpene or phenolic actives owe their effects to multifarious synergies between their component chemicals and this factor, along with an inability to reliably standardize extract constituents, has to date constrained their development and the clarity of the literature on their efficacy in humans.

The development of effective plant-based products for improving human brain function is constrained by a number of issues, including a need to definitively identify relevant active components and understand synergies within them and an inability to adequately standardize replicable extracts. It is evident that insects such as *Drosophila* and the honeybee are sensitive to modulation by a full range of pharmacological agents. However, insect behavioral studies have only involved secondary metabolites either as a consequence of using them as simple tools for the modulation of specific neurotransmitter targets or alternatively in insect models of drug abuse and addiction (Table 1). It would seem appropriate that insect models could be

utilized as simple, economical, time-efficient, and ethically acceptable tools for investigating the neuronal and behavioral consequences of individual phytochemicals and complex mixtures. It is also evident that there are many viable terpene/ phenolic extracts that may have beneficial effects on CNS function without the toxicity associated with psychoactive alkaloids. These may include complex chemical mixtures that attract symbiotic insects and potentially offer them cognitive benefits. However, many phytochemicals simply do not function effectively as single molecules and there are many examples of synergies within and between the chemical groups. Insect models may provide ideal starting points for disentangling these synergies prior to animal and human studies.

Many secondary metabolites are also expressed as a consequence of environmental stressors, and an increased understanding of the many and varied ecological roles of secondary metabolites should, in the future, make it practical to upregulate and standardize the levels of desired active components by introducing a variety of stressors such as herbivore attack, salinity, UV light, bacteria, or fungi in carefully controlled environments. Finally, the vast majority of the voluminous research relating to the topics briefly reviewed above is conducted in entirely discrete discipline “silos.” In terms of research relevant to brain function, the vast majority is basic laboratory research conducted in vitro/vivo in an entirely atheoretical context, often with parent molecules or chemical concentrations that are highly unlikely to be seen in the human brain. Asking the simple question of why plant chemicals modulate brain function can only serve to focus some of this huge research effort, with the integration of thoughts and concepts from a diverse range of disciplines, including molecular biology/biochemistry, plant science, zoology, entomology, pharmacology, medicine, neuroscience and psychology potentially offering an intellectual synergy that might move this area a step forward.

ABSTRACT

Stroke is the third cause of death and leading cause of chronic disability throughout the world, affecting 15 million people each year. The established risk factors for stroke include hyperlipidemia, dyslipidemia, arterial hypertension, diabetes mellitus, cigarette smoking, micro-vascular rupture, age and observed comorbidity. Although many agents have been used since long for treatment of different cerebrovascular and neurodegenerative diseases but, their effectiveness and safety has attached a great concern from scientists and researchers. Therefore, developing novel classes of anti-inflammatory, anti-oxidative and hypolipidemic neuroprotective agents which possess high efficiency and fewer adverse effects has still been a focus for the preventive treatment of stroke. A variety of herbs and prescriptions have been demonstrated to have neuroprotective effects *in vivo* and *in vitro* that may be relevant to the treatment of stroke. Oxidative stress and inflammation has been increasingly recognized to be the key elements in pathological progression of ischemic stroke. Thus, tackling dyslipidemia, hypertension, reducing oxidative stress and downregulating the inflammatory response are options that merit consideration as potential preventive measures/targets for ischemic stroke. Despite technological developments; herbal drugs still occupy a preferential place in a majority of the population in developing countries and terminal patients in the West. Herbal drugs, in addition to being cost effective and easily accessible, have been used since time immemorial and have passed the test of time without having any side effects. The multi-target effects of herbs (holistic approaches) are the fundamental basis of their

utilization. This approach is already used in traditional systems of medicine like Ayurveda, which has become more popular in the West in recent years. The treatment of cerebral ischemic disease by natural medicines has a long history, and has accumulated a rich theoretical knowledge and treatment experience. The objective of this chapter is to critically evaluate the experimental research situation of the protective effect of the individual compounds from natural medicine on cerebral ischemia in the recent years, emphasizing the major mechanisms underlying cerebral ischemic pathophysiology. Many representative compounds from natural herbs which are often used to treat stroke are discussed in detail. The results indicate that these components possess a protective effect on cerebral ischemia, and that these components have different mechanisms, including inhibiting excitotoxicity by ginkgolide B, anti-apoptosis of breviscapine, influencing astrocytic activation and proliferation of tanshinone IIA, influencing free radicals by ginsenoside Rd, impairing blood-brain barrier disruption by baicalin, and the anti-inflammatory activity of tetramethylpyrazine. Moreover, some components have multiple neuroprotective mechanisms. Therefore, the combination of individual compounds from natural medicines, considering the mechanisms of cerebral ischemia, may be beneficial to patients with cerebral ischemia in the future. This approach for screening herbs to investigate for prevention and treatment of stroke is a relatively successful method for the identification of herbs and single compounds. Therefore, natural herbs/agents that have a wide spectrum of inhibitory actions on dyslipidemia, hypertension, oxidative stress, inflammation and blood clot dissolution may be useful as preventive medicine and in protecting/rescuing neuronal cells. Here in this chapter we will present a detailed account of the use of natural herbs with multiple effects/targets and different modes of action in reducing the risk factors and prevention of stroke and other cerebrovascular diseases.

We will also evaluate the preventive neuroprotective effect of these plant extracts on reducing the risk factors of stroke and prevent cerebral injury in animal models and humans.

INTRODUCTION

Neurological disorders pose a significant threat in the modern day arena. Cerebral ischemia is the third cause of death and leading cause of chronic disability throughout the world. It involves disruption of the blood flow to the brain with rapid depletion of cellular energy and glucose, resulting in ionic disturbances which in turn initiate a cascade of detrimental events [1]. Stroke has become one of the leading causes of serious, long-term neurologic impairment and functional disability and is the cause of mortality globally. Depending on the severity and type, stroke can leave an individual with a residual damage of physical, psychological, social and cognitive functions [2]. However, there are no known drug therapies to improve recovery after stroke. The established risk factors, including arterial hypertension, diabetes mellitus, cigarette smoking, micro-vascular rupture, hyperlipidemia/dyslipidemia, age and observed comorbidity, such as sickle cell disease, HIV infection and cerebral malaria are increasingly being encountered in the tropics [3].

Cerebral ischemia initiates a cascade of detrimental events including glutamate associated excitotoxicity, membrane lipid degradation, DNA damage, formation of reactive oxygen species and acute inflammation, which lead to the disruption of cellular homeostasis, progressive cell destruction and consequent neurobehavioral impairments. Increased oxidative stress and inflammation has been regarded as an important underlying cause for neuronal damage induced by cerebral ischemia/reperfusion (I/R) injury.

Hence these are increasingly recognized to be the key element in pathological progression of ischemic stroke. In cerebral ischemia and reperfusion (I/R) injury, inflammation is an important pathological process contributing to neuronal cell death and neurovascular injury as well as affecting the progress of neurogenesis and brain repair. Activated inflammatory cells secrete many inflammatory factors including cytokines, chemokines, enzymes, free radicals and other small molecules, subsequently facilitating inflammatory process and accelerating the Blood Brain Barrier (BBB) breakdown, neuronal cell death or affecting brain repair [4].

Therefore, targeting inflammation and related factors could be a crucial therapeutic strategy for preventing and treating brain damage and promoting brain repair. Natural herbs provide a rich source to attenuate lipidemia, neuroinflammation and prevent aggression of cerebral ischemia-reperfusion injury.

Dyslipidemia is characterized by elevated level of total cholesterol (TC), triglyceride (TG), low-density lipoprotein cholesterol (LDL-C) and by lowering level of high-density lipoprotein cholesterol (HDL-C) in serum. Dyslipidemia is one of the major independent risk factors for coronary heart disease (CHD) and stroke [5].

As per American Heart Association (AHA) 2013 Guideline on the Treatment of Blood Cholesterol to Reduce Cardiovascular Risk in Adults” emphasized that the progressively regulating dyslipidemia is the pivotal controlling method for risk factors of ischemic cardiovascular events [6]. Antioxidant and antiinflammatory based drugs and formulations for the prevention and treatment of complex neurological diseases have appeared during last three decades. A number of plant products including polyphenols, terpenes, flavinoids and various plant extracts exert antioxidant, antilipedimic, antiinflammatory actions but till date no effective therapy is available against stroke.

Recent advances in the stroke medicine have highlighted the role of acute transitory inflammation in the cellular pathology following ischemic stroke [7]. It is imperative that acute inflammation might potentiate or perturb the already initiated exitotoxicity. TNF- α has been correlated with cerebral ischemic injury [8]. The advent of inflammation with the proven oxidative conditions can exacerbate the extent of neuronal death. Antioxidant and anti-inflammatory based drugs and formulations from plant sources for the prevention and treatment of complex neurological diseases like stroke, Alzheimer’s and cancer have appeared during last three decades [9]. But till date no drug has been successfully approved for the treatment of stroke therapy. This envisages that there is great scope for finding new therapies for the treatment of cerebral ischemia. Recent studies have shown that a number of plant products including polyphenols, terpenes and various plant extracts exert an antioxidant and anti-inflammatory action [10, 11]. There is also a considerable amount of evidence revealing an association between individuals who have a diet rich in fresh fruits and vegetables and the decreased risk of cardiovascular and other diseases [12, 13].

Despite technological developments, herbal drugs still occupy a preferential place in a majority of the population in the Developing Countries and terminal patients in the West. Herbal drugs, in addition to being cost effective and easily accessible, have been used since time immemorial and have passed the test of time without having any side effects.

The multi-target effects of herbs (holistic approaches) are the fundamental basis of their utilization. This approach is already used in traditional systems of medicine like Ayurveda, which has become more popular in the West in recent years. Natural extracts from genus

Elsholtzia, Scutellaria, Pinax and Artemisia have recently been found to possess strong antilipidemic, antioxidant and anti-inflammatory effects.

Modulation of antilipidemic, oxidative/inflammatory response by these cocktails of natural herbs through different mechanisms in the prevention of stroke may be of vital significance. Here in this chapter we present a detailed account of natural herbal and herbal cocktails in preventing the stroke. Overall, this may help us to understand and find new plant based antilipidemic, antioxidant and anti-inflammatory agents for preventing stroke and other cerebrovascular diseases. A novel herb belonging to critically endangered species Artemisia has been shown to possess very high antioxidant and antiflammatory activity. Very recently Artemesia species from Astereaceae family has been shown to possess anti-oxidant and antiflammatory properties in various in vitro models of cancer and obesity but not against the cerebral ischemia [14, 15]. The plant extract from Artemisia are used locally for the treatment of epilepsy, piles, nervous disorders, cough, cold, fever, and pain [16]. The therapeutic efficiency of some herbs may, in part, be mediated via their influence on the immune response, since some of these plants can affect the immune reactions through their anti-inflammatory actions. The plant had shown anti-inflammatory and also immunosuppressive activity [17].

Other herbs of the genus Pinax (Araliaceae) have been shown to have protective effect on ischemic brain damage in vivo [18] and focal cerebral ischemia [19] Ginseng has neuroprotective effects in transient focal or global cerebral ischemia [20]. Red ginseng powder, which is steamed ginseng under pressure, also prevents delayed neuronal death in gerbils. Ginsenoside Rb1 protects the brain from reversible focal brain ischemia in rats [21] and protects hippocampal CA1 neurons by scavenging free radicals [22].

Herbs of the genus Elsholtzia (Lamiaceae) have a long history of medicinal use in folk. The phytochemical investigations has revealed the presence of flavonoids, phenylpropanoids, terpenoids, and other compounds. Crude extracts from the genus exhibited a wide spectrum of in vitro and in vivo pharmacological activities. As folk medicine, the plants in the genus have been used for the treatment of colds, headaches, pharyngitis, fever, diarrhea, digestion disorder, rheumatic arthritis, nephritises, and nyctalopia in China.

The herb Polygonum cuspidatum (PC) is derived from the dried root and rhizome of Polygonum cuspidatum Sieb. Et Zucc. It dispels wing dampness, removes stagnation, relieves pain, and reduces phlegm. Polydatin and resveratrol, the primary active components of PC, inhibited the cholesterol absorption from intestinal tract [23]. Du et al., found that polydatin administrated orally significantly decreased TC, TG, and LDL-c levels and increased TC/HDL-c ratio in hyperlipidemic hamsters and rabbits [24]. It was also reported that the Polygonum cuspidatum water extract (PCWE) reduced the cholesteryl ester formation in human hepatocytes by inhibiting A-cholesterol acyltransferase activity (ACAT) in HepG2 cell in vitro, and PCWE inhibited ACAT activity by 50% [25].

Recent progress in mass analytic technologies for studying complex systems provides novel platforms for drug discovery from herbal medicine. The comprehensive matrix analytic technologies, such as LC-MS, DNA microarray, proteomics, metabolomics, etc., offers new opportunities to explore the active compounds and their molecular targets, facilitating drug discovery for stroke treatment. Therefore, studies on the therapeutic strategies of herbal medicine not only provide novel clue to find active compounds to prevent hyperlipidemia, neuroinflammation and protect neuronal cells from ischemic brain injury, but introduce a new strategy for drug development targeting multiple neuropathological pathways including

hyperlipidemia, anti-oxidative stress and neuroinflammation in the treatment of ischemic stroke.

Therefore, reducing hyperlipidemia, reducing oxidative stress and downregulating the inflammatory response are options that merit consideration as potential preventive/therapeutic targets for ischemic stroke.

Consequently, agents capable of modulating both elements will constitute promising prevention/therapeutic solutions because clinically effective neuroprotectants have not yet been discovered and no specific preventive therapy for stroke is available to date.

APPROACHES FOR PREVENTION AND TREATMENT OF STROKE

Two major approaches have been developed in ischemic stroke. The first is to establish reperfusion by dissolution of the clot using thrombolytic drugs. At present, rt-PA is the only thrombolytic drug approved for the treatment of acute ischemic stroke; rt-PA administration is restricted to within 3 h of stroke and its use increases the risk of hemorrhagic transformation [26]. The second approach is to develop neuroprotective agents that interfere with the biochemical cascade of events that leads to cell death in the penumbra area that surrounds the core. This protection would attenuate lots of the clinical problems of stroke, including motor disability and spatial hemiplegia. However, although more than 37 potential neuroprotective agents have been studied in more than 114 clinical trials [27], none of them is clinically efficacious and in use in the Western world [28]. In Far Eastern countries such as Korea, China, and Japan, stroke has been treated by traditional Eastern medicine (TEM) for thousands of years. TEM is also known as traditional Chinese medicine (TCM), traditional Korean medicine, Sino-Japanese medicine, oriental medicine, traditional herbal medicine, and traditional Asian medicine. In China, traditional medicine is prevalent; approximately one third of patients are treated with traditional medicine [29], and in Korea, 25% of stroke patients also visit traditional medicine doctors [30]. Extensive experience and abundant clinical data on stroke treatment have been accumulated on TEM. Basic and clinical research in TEM constitutes a potentially rich source of drug discovery and development with the integration of TEM and western pharmacology. In recent years, many attempts have been made to document research data about extracts of composite formulas, single herbs, or single compounds from TEM herbs according to orthodox pharmacological actions. Groups of TEM herbs have been identified as potential sources for compounds with predominant effects on the circulation, thrombogenesis, inflammatory processes, and neuroprotection.

This chapter reviews herbs and prescriptions that have been screened for neuroprotective effects *in vitro* and *in vivo* in ischemic model systems and the neuroprotective compounds isolated from them. Neuroprotective mechanisms of prescriptions, herbs, and single compounds relevant to the treatment of brain ischemia, including antioxidant, antiexcitotoxic, and anti-inflammatory effects are also discussed.

IMPORTANCE OF TRADITIONAL MEDICINE

Traditional medicine (TM) is a comprehensive term used to refer both to systems such as traditional Chinese medicine, Indian Ayurveda and Arabic Unani Medicine, and to various forms of indigenous medicine.

In countries where the dominant health care system is based on allopathic medicine, or where TM has not been incorporated into the national health care system, TM is often termed "complementary," "alternative" or "non-conventional" medicine [31]. The links between TM and biodiversity are exemplified by a long tradition of healing powers associated with the earth's natural systems, whether this entails medicinal plants and animal species, the ambient salubrious air, spring water or the natural scenery. The pharmacopoeia of folk seties as well as professional medical systems like Chinese, Ayurveda, Unani and biomedicine contain thousands of medicines made from leaves, herbs, roots, bark, animal materials, mineral substances and other materials found in nature [32, 33]. The interconnections between TM and the biotic environments may be seen in the health benefits derived from the existence of a full complement of species, intact watersheds, climate regulation and genetic diversity, as well as through our fundamental needs for food, water, clean air, shelter and relative climatic constancy [34]. Discussions of the links between TM and biodiversity therefore are imperative [35], particularly when considering the importance of the former as a source of primary health care to 80 percent of the world's population [36]. The treatment of cerebral ischemic disease by natural medicines has a long history, and has accumulated a rich theoretical knowledge and treatment experience. In recent years, a drive to "modernize" this ancient form of medicine in China has been gaining momentum.

Separation of the chemical constituents of natural medicines and their application to specific health problems (including the treatment of cerebral ischemic disease) is promoted worldwide. With the development of research methods and experimental technology, this process will also broaden mechanism research. Table 4.1 summarizes the studies on various individual compounds from natural medicines that are commonly used in experimental research for the treatment of cerebral ischemia. The following section of the chapter aims to summarize the pathophysiology of cerebral ischemia, and to outline the experimental research situation on the protective effect of cerebral ischemia by individual compounds derived from natural medicines. The various compounds derived from the natural herbs highlighted in Table 4.1 have a great potential for the protection from and treatment of cerebral ischemia. Individual compounds derived from natural medicines, such as ginkgolide B, breviscapine, tanshinone IIA, baicalin, and ginsenoside Rb1 protected from ischemic cerebral injury by the different pathophysiologic mechanisms in experimental studies. This fully illustrates that compounds derived from natural medicines for the protection of cerebral ischemia have broad prospects.

The discovery of the effects of the compounds described here are certainly useful achievements, however, there are also some shortcomings, such as the reproduction of the animal models and the clinical guidance. Furthermore, compound preparation is difficult for the international market due to the fact that the international approval, to date, only applies to treatment with single compounds. Cerebral ischemia is a multifactorial disorder which includes several pathways for the progression of injury to brain cells. Many basic scientists have approached natural medicine as a vast, but largely untapped, source of natural products
